medical schools. The other four are associated with medical schools: Newington, Connecticut, under Yale, White River Junction, Vermont, under Dartmouth, and Cushing and West Roxbury under a joint committee from Boston University, Harvard and Tufts.

A most praiseworthy feature is the comparative autonomy of the medical schools. They have no contract with the United States Government, but they have complete responsibility for all professional appointments in the affiliated hospitals. Consultants and attending surgeons and physicians are nominated by the dean's committee. The appointment of the full-time professional chiefs is authorized by the Veterans Administration only after approval by the dean's committee, the Branch Medical Director and the Hospital Manager. Residents are selected by the chiefs of services with the approval of the dean's committee. Furthermore the medical schools through the dean's committee and the professional staffs are authorized to supervise the teaching programs and to direct the expenditure of research funds. Thus, without asking anything in return the Government has given the professional supervision of the affiliated hospitals to the medical schools.

In addition to the consultants appointed by the medical schools there are, as mentioned above, those appointed by the Veterans Administration to act as professional advisers to the Chief Medical Director in Washington and to each of the 13 regional divisions of the Veterans Administration, the branch offices. The national or central office consultants are chosen by the Medical Director in Washington. The branch consultants are appointed by the Chief Medical Director after recommendation by the national consultants and with the approval of all the medical schools in that particular branch. They make detailed surveys of all hospitals in their respective fields and render reports to the branch director. They have direct professional supervision of the nonaffiliated hospitals. However, lest they interfere with the dean's committees they have no professional authority over the affiliated hospitals. As there is no established channel for direct communication between the branch consultants and the dean's committees occasional misunderstandings have arisen and in some areas it has been suggested that the former restrict their activities to the nonaffiliated hospitals.

Actually, the branch consultants, by visiting all the hospitals and maintaining a close contact with the administration, should acquire a valuable breadth of view and be in a position to clarify many problems that appear to be administrative but affect the care of patients. A recognized channel of communication between the dean's committee and the branch consultants would lead to a better integration of the consultant program. The simple expedient of having the senior consultants ipso

facto members of the respective dean's committee would avoid an unnecessary link in the chain and would provide a ready means of contact between the branch consultant and the dean's committee. In hospitals where the senior consultant in surgery is a member of the dean's committee (Yale, Dartmouth—Fig. 1) such a contact has naturally developed and has been mutually beneficial.

An immediate result of the affiliation of Veterans Administration hospitals with the medical schools was an extraordinary improvement in caliber of the professional personnel. In 1945 there was hardly a qualified surgeon in the New England Branch. There were none recognized as such by the American Board. Now all the full-time chiefs of surgery in the affiliated hospitals are well known men with distinguished records of individual accomplishments. Assisted by able consulting and attending staffs, they have established surgical services comparable to those in the best university hospitals.

The part of the hospital consulting and attending surgeons is a vital one. The consultants are men with established reputations as surgeons and teachers. They supervise the teaching, act in an advisory capacity and occasionally carry out surgical procedures of an unusual or formidable nature. In short, they bring the medical school to the hospital. The attending surgeons, in general, are a younger group. Free from administrative responsibilities, they do the bulk of the daily bedside operating-room instruction but do very little surgery themselves. It may be well to emphasize that an attending surgeon cannot be a man of limited experience hoping to broaden himself by operating in the Veterans Administration hospitals. He must be an accomplished surgeon, capable and willing to teach. His role is a comparatively selfless one.

The consulting and attending surgeons receive a per-diem allowance of \$50 and \$25, respectively, for their services. Since each visit consumes the better part of a day in ward rounds, at clinics or in the operating room the financial return cannot compare with that in private practice. Moreover, in assaying the cost of the consultant program to the Government one must remember that prior to the new regime a consultant was paid for his services by the operation. He might receive as much as \$500 for a major procedure. Now he conducts rounds, gives a clinic and assists at or performs the surgery for \$50 or \$25.

The accomplishments of the reorganized Department of Medicine and Surgery are best measured by improvements in the standards of care offered to the veterans. A detailed comparison between the old and the new would serve no useful purpose and is hardly possible since the older records are not adequate for analysis. The figures from a survey of the hospitals (Table 1) are indicative of the general trend showing a large increase in the volume

clinical material, a reduction in the number of deaths and a gratifying increase in the percentage of autopsies performed.

The record at present speaks for itself and since the findings appeal to the surgical mind more than a bare list of figures, a broad indication of the type of surgery now being done in the affiliated hospitals is presented in Table 2. The data include all opera-

performed for gastric or duodenal ulcer in the two years in this branch. Since patients are usually admitted to these hospitals unless their symptoms indicate failure to respond to therapy, the number of cases in which surgery was done iservative. Time does not permit a detailed breakdown of the material, but the figures for gastric resection include 2 for gastrojejunocolic anastomosis and 8 for acute massive hemorrhage. The

quality of care for acute perforation is exceptionally low and the over-all mortality is most gratifying. An interest in research is characteristic of good hospitals and to a certain extent is a reflection of high standards. It is significant that two papers presented at this meeting yesterday. To date, five papers have been published from the surgical service of the four affiliated hospitals. An additional sixteen papers covering a wide range of topics are in process of publication. Recently funds have become available for laboratory studies and special projects so that the future should see a considerable amount of valuable research done in these institutions.

From the foregoing, it is obvious that the surgical standards and standards of the affiliated Veterans Administration hospitals are excellent for training

residents if the variety and volume of clinical material are adequate. There is an unusual number of rare and interesting cases, a steady flow of the simpler types of surgery and an abundance of gastric and vascular work. The amount and type of material available in general surgery is indicated in Table 3, which lists the operations performed by the chief residents in one month in two different hospitals. Similar data could be produced for the subspecialties of urology and orthopedics, which are well represented in the majority of the Veterans Administration hospitals. Finally, there is ample material for training in roentgenology and pathology. Unfortunately, however, the restriction of the clinical material largely to one sex and certain age groups makes it essential for each resident to obtain a part of his training elsewhere. Despite this drawback, an increasingly larger number of able young men are seeking residencies in these

hospitals and a means of providing them with a balanced training through affiliation of the Veterans Administration hospitals with civilian institutions is highly desirable. The Dartmouth Dean's Committee has taken the lead in this respect by establishing a unified residency between the Hitchcock Hospital and the Veterans Administration Hospital at White River Junction. All their residents are now assured a three-year graded service, which includes work at both hospitals. It is urgently hoped that other institutions will see fit to do likewise.

The large volume of excellent teaching material in the Veterans Administration hospitals makes them especially suitable for affiliation with well staffed community hospitals that may not have large ward services. It is sincerely hoped that under the supervision of the universities affiliations can be established between outstanding community hospitals and the Veterans Administration hospitals that are not, at present, associated with medical schools. Unless this can be worked out, the future of the nonaffiliated Veterans Administration hospital is an unhappy one.

The wisdom of linking the Veterans Administration hospital to the medical schools is shown by the present plight of the nonaffiliated hospital at Togus, Maine. The clinical material in this hospital is comparable to that in any of the affiliated hospitals. The full-time Chief of Surgery is well trained, competent and conscientious, and there are a number of able consultants who visit the hospital regularly. A well conceived program of lectures, ward rounds and clinics is established, but because the institution is not a dean's committee hospital it is not authorized to appoint interns or residents. Consequently, the members of the regular full-time staff are overwhelmed in providing the elementary details of good care. Naturally, it is difficult to keep an able staff in such circumstances. The present chief of surgery remains because it is hoped that sooner or later a residency-training program can be instituted. If he should leave, it would be difficult to persuade a well trained and competent surgeon familiar with the situation to succeed him.

The future of the hospital at Togus and other hospitals to be set up in this branch is dependent upon an affiliation with one or more of the universities. Geographic proximity, although desirable, would not be essential. The moment a hospital is authorized for resident training, defects in the full-time staffs can be corrected because well trained men are willing to take positions in dean's committee hospitals. An able resident staff could then be appointed, and in a very short time the atmosphere and standards of these hospitals would compare with those of the other affiliated hospitals.

If one excludes the nonaffiliated hospitals from the discussion, it is evident that the reorganized department of medicine and surgery in the Veterans Administration has fulfilled expectations. It has attracted distinguished staffs, offers excellent opportunities for training and research, and provides the veteran with the highest quality of care. It deserves a continued and expanding support from the universities and the medical profession.

On the other hand, it would be a mistake to conclude that the notable achievements of the Veterans Administration hospitals are examples on a small scale of what a system of socialized medicine could do for the country as a whole. The record of the Department of Medicine and Surgery has been made despite the fact that it is a governmental system and not because of it. From the very beginning of the new regime, General Paul R. Hawley with the approval of General Bradley insisted that the "red tape" of administrative details be reduced to a minimum and that nothing should hamper the professional personnel in their work. Despite the fact that this policy, vigorously supported by Mr. Gray and Dr. Magnuson, has permeated the entire organization there is a constant struggle between the professional personnel and the Frankenstein of any governmental system.

Thus, elaborate checks and safeguards must control the spending of money that belongs to people of the United States. A new budget must be approved each year by Congress and shared with other departments. It may be exceeded before the end of the fiscal year and sudden precipitate reductions in personnel and travel may occur. Although doctors and nurses are not affected by unique rules and regulations of civil-service employees may shift key technicians or secretaries to other positions and replace them with less suitable people. Moreover, someone must be accountable for the property of the United States Government and despite every effort to minimize it some of the responsibility falls on the shoulders of the professional staff. The financial department requires consultants and attendants to sign in and out and cannot conceive of a doctor visiting a hospital for other than personal remuneration. Pay ceilings, as well as a forty-hour week for each employee, place a serious limitation on the work that can be done in the operating room. There are also intended building regulations, which if literally interpreted may create the most preposterous conditions. In one hospital the use of a badly needed autoclave was delayed for more than a year because of an apparent lack of authority to make a hole through a wall.

Since these are Government hospitals it is essential for the managers to have more authority than the director of a civilian hospital. They are to sense the director and the hospital trustees as one. Fortunately, the hospital managers in this branch have been well chosen, and excellent relations between them and their service chiefs have developed. But there are potentialities for discord, and should a manager prove to be dictatorial and unsympathetic with the aims of the professional services, he could make the lives of his service chiefs miserable. Moreover, it would take time to untangle such a situation. Furthermore, both managers and professional chiefs are subject to the unintended influence of Congressmen and service organizations who with the best of intentions may unwittingly interfere with the care of patients. What of all, even the consultants, because there is a fear of governmental authority in their suggestions many times may be more confusing than helpful.

These are not criticisms of the Veterans Administration. These are facts that, so far as it is humanly possible, the medical director of the Veterans Administration and his department chiefs have endeavored to eliminate. In this connection it should be stated parenthetically that if the Department of Medicine and Surgery had its own budget under the direction of the Chief Medical Director, a great many of the administrative difficulties that beset the hospitals could be eliminated. But the best of governmental systems is hard to correct. It requires constant and determined resistance.

It takes a strong, patient and selfless man to a permanent position as chief of surgery in the Administration. As long as the organization is comparatively small and administrators like Dr. Hawley and Dr. Magnuson remain at the helm, and as long as the universities continue their

support, it is hoped that enough able men will be found for these positions to assure the high standards of care that Elliott Cutler envisioned. To expand this system to all the people would be disastrous. The machine would control the men, and the care of patients would be in the grip of an automaton.

ARACHNIDISM*

Effect of Calcium Gluconate in Six Cases

WILLIAM E. R. GREER, M.D.†

BOSTON

ARACHNIDISM, the syndrome following the bite of a black-widow spider, is a definite clinical entity in the field of general medicine. The bite of the spider *Latrodectus mactans*, found in all but seven states in America, is poisonous. It has been recognized for centuries.¹ Bequaert's² review of the literature in 1926 threw much skepticism attached to the fact that such a creature could, by its bite, produce territorialized symptoms in man. He reported 380 deaths in 17 states in eighteen states. It remained unexplained,³ in 1933, to dispel all doubt concerning the seriousness of this arachnid menace to man. He described the clinical syndrome that follows the bite of a female *L. mactans* after application of the spider to his own finger.

The distribution of *L. mactans* in the United States is wide; this spider has been found in California, Nevada, Arizona, Utah, Colorado, New Mexico, Kansas, Oklahoma, Texas, Arkansas, Louisiana, Mississippi, Alabama, Georgia, Florida, Tennessee, North Carolina, South Carolina, Kentucky, Virginia, West Virginia, Maryland, Delaware, Pennsylvania, New York, Massachusetts (Cape Cod and New Hampshire, among other states). Four et al.⁴ reported that the black-widow is greatly increasing in numbers and invading the large cities. These spiders are found in great numbers in the vicinity of human habitations, not only in outdoor privies, as was formerly believed, but also in beds, garages, automobiles and even high in office buildings.⁵

Although limited in practical application to cases where this spider is indigenous, knowledge of the clinical entity is important since many spider bites are subjected to needless operations because the symptoms often simulate acute surgical lesions of the abdomen. Almost every article in the literature concerning the acute abdomen includes

arachnidism to be considered in the differential diagnosis. If excruciating abdominal pain overshadows the rest of the syndrome surgical operation is often accomplished. An appalling record of human suffering has been checked back to *L. mactans* and its prototypes.⁶

The cases of arachnidism reported represent but a small fraction of the actual number that have occurred, many other cases noted by personal communications are never published. The arachnid menace is more extensive than one would expect. Its curtailment in an indigenous area can only be accomplished by unified efforts of mankind and parasitic enemy insects of the black-widow spider.

Evidence for the incidence of arachnidism rests largely on the statement of patients who have been bitten describing the insect answering the description of *L. mactans*. In other cases observers or the victim have caught the spider and brought it to proper authority to be identified.

In spite of the prevalence of the black-widow spider throughout North, Central and South America and especially in the southern half of the United States, relatively incomplete knowledge existed concerning its life history until the work of Blair.⁷ The species *L. mactans* have been found in dark corners and in clothes closets. They are cannibalistic, feeding on each other whenever the opportunity presents itself. The nickname "black widow" given to the female of the species arises from its habit of capturing and feeding on the much smaller male after he has served the ends of species preservation.

The globose abdomen of the female stands out like a highly polished black pearl. It is attached by a slender pedicle to the smaller cephalothorax. The body averages 1.27 cm. in length. The abdomen is about 0.9 cm. in length. Slender pointed legs when expanded have a span of 3.8 to 5.1 cm. Legs and body are a glossy black and are covered by short, black hairs. On the ventral surface of the abdomen there is a rich red marking resembling an hourglass. Dorsal to the spinnerets in the midline of the convex

* the Robert Dawson Evans Memorial Massachusetts Memorial Hospital and the Department of Medicine Boston University School of Medicine

† Director in Medicine Boston University School of Medicine Residency in Medicine Robert Dawson Evans Memorial Massachusetts Memorial Hospital

surface of the abdomen is an additional red marking

The full-grown female, particularly when distended with eggs, appears from experiments with animals to be the most poisonous. It is, however, a timid creature and when disturbed makes every effort to escape, this explains the relatively few bites in spite of the prevalence of this arachnid. When cornered or compressed, as between skin and clothing, the spider bites in self-defense. The male is ignored as an etiologic factor of any importance because of its size, timidity and scarcity.

The potent nature of the venom is readily appreciated when one sees a victim of the black-widow spider about an hour after a bite. The victim writhes in agony, terror-stricken, and expressing

the clinical picture into three stages: the stage of lymphatic absorption of the injected venom, characterized chiefly by pains in the bitten area and absence of systemic effects; the stage of vascular dissemination, characterized, clinically, by the explosive onset of widespread agonizing muscular pains and a condition of profound shock depending on the quantity of the venom or its toxic products; and the stage of elimination of the venom or its toxic products, characterized clinically by hypertension, diaphoresis, gradually diminishing muscular pain and evidence of renal damage—this stage is suggestive of an acute toxic nephritis.

REVIEW OF CASES

The syndrome, as presented by 6 patients bitten by the black-widow spider observed in a seven-day period in an overseas tropical area, usually followed a similar pattern: transient excruciating local pain at the site of the spider bite, rapid local edema and redness of the skin at the site—in 2 cases the site could not be identified, in ten to fifteen minutes a "burning sensation" that spread centrifugally from the site of the bite and soon involved the whole body, passing off in about twenty to thirty minutes; a sudden abdominal pain, often cramp-like as in an acute surgical condition of the abdomen, cramp-like pains in the legs, arms and back, a general feeling of "utter weakness", restlessness and extreme fear reaction, often hysteria, headache, nausea and vomiting, and burning of the soles of the feet (in unknown types of bites this symptom may be pathognomonic).

In children there may be convulsions, which are extremely difficult to control.¹¹ Other possible symptoms are variable such as paralysis, cyanosis, dyspnea and urinary retention.

Physical examination in this series revealed the following: the site of injection usually showed an area of erythema with mild edema (in 2 cases the site was not evident), a board-like abdomen, non-tender to palpation, was present in all cases; there was hypersensitivity of the skin, the calf muscles were tender to palpation, 2 patients were in profound shock with blood pressure unobtainable (the other 4 patients had normal or slightly elevated blood pressures), motion of extremities was limited by muscle spasm, and flexion was a prominent feature, the temperature was normal or only slightly elevated, the pulse was slow, being 80 or under in all cases, examination of the blood showed a moderate leukocytosis, and the 2 patients presenting a picture of profound shock showed albuminuria.

The victims all gave an excellent history, and in all cases the spider was identified. One patient described his episode as follows:

I was putting on my shirt this morning when I felt as if someone had stuck a needle in my shoulder. When I tore off my shirt a black spider with a red-orange spot on its belly fell out. The place stung for about 10 minutes,

*Adapted from Macchiavello *

fears of death. Thesing⁶ states that the venom of the female of this species is fifteen times as potent as that of a rattlesnake. The venom has been stated to be a toxalbumin with its most damaging activity on nerve endings. It is a thick, translucent, oily, lemon yellow-colored fluid, acid in reaction, from which a hemolysin and arachnolysin have been isolated.⁸ A report by Macchiavello,⁹ showing the results of spontaneous or induced stinging of guinea pigs by spiders, is indicative of the formidable nature of *L. mactans* (Table 1). The bite of the *L. mactans* produced the same nervous symptoms in the guinea pig as it did in man, death occurring between four and eighteen hours.

Other authors cited by Blair³ have found similar results in experiments with warm-blooded animals. Experimental studies by Blair showed marked reactions in mice, rats, guinea pigs and chickens. In mice the mortality was practically 100 per cent. Rabbits, cats, dogs and sheep seemed little affected. Baerg¹⁰ gave experimental evidence when, on July 9, 1922, after several attempts, he induced a black-widow spider to bite his finger for about five seconds, sharp pain in the finger and hand being the most prominent symptom, followed by aching pains in the muscles of the lumbar region, shoulders, chest and legs.

It was Blair,³ in 1933, who allowed a black-widow spider to bite him in an experimental study and recorded careful clinical observations dividing

and then a burning sensation spread all over my arm and soon over my whole body. I began to get stomach cramps and my legs ached. Soon I felt weak and dizzy and wanted to sleep but headache and a feeling of terrible nausea came over me.

The patients in this series were immediately given 10 cc of 10 per cent calcium gluconate intravenously. Subsequently they were given a saline infusion containing 10 cc of 10 per cent calcium gluconate. An ice bag was applied to the affected area. Relief was obtained in a short time in all cases and was followed by profound sleep. The patients were out of bed the next day and back to duty on the fourth day. Even the 2 patients in profound shock responded. No morphine was used, and antivenin was not available.

DISCUSSION

The venom has previously been reported to have injurious effects on the isolated heart of the frog.¹² Billman⁸ reported a case with suggestive changes in the electrocardiographic tracing and recommended that more emphasis be placed on the cardiac status in arachnidism. Precordial and epigastric oppression are not uncommon. Bradycardia has frequently been noted by other observers.^{2, 13, 14} In this series normal pulse rate or bradycardia was common.

Blair³ believes that the condition of shock, characteristic of the second stage, suggests the presence of a histamine-like substance in the spider venom. Such a possibility is enhanced by the secretagogue action, evidence of contraction of the bronchial and intestinal musculature and symptoms of acute prostration noted in animal experiments. Indeed, Essex and Markowitz¹⁵ observed certain histamine-like properties of another secretion, crotalin (rattlesnake venom), in experimental studies.

The clinical picture of the development of an acute toxic nephritis has caused much speculation. Other observers¹¹ considered the syndrome to be like hypertension in the adult and eclampsia in the child (children often have convulsions in arachnidism). Four of the 29 cases reported by Walsh and Morgan¹² and 2 of this series showed albuminuria. These findings may be similar to the "allergic nephritis" seen after bee stings.¹⁶

Another clinical syndrome noted in arachnid poisoning is cutaneous arachnidism, or the gangrenous spot of Chile.⁹ Three types of arachnidism have been noted in Chile: nervous arachnidism, produced by the poison of *L. mactans*, cutaneous arachnidism or gangrenous spot, caused by the spider *Loxosceles laeta*, which injects a local necrotizing poison, and viscerocutaneous arachnidism, the intermediate type, in which the patients, in addition to cutaneous signs, showed symptoms of hepatitis with jaundice, hematuria, fever and slight nervous disorders. *L. laeta* is a house spider. There is often a painless latent period after the bite of the black-widow spider, but this never occurs with cutaneous arachnidism. There is absence of general

symptoms in the "gangrenous spot of Chile," but the local necrotizing lesions are severe. The bite is followed by immediate changes in the surrounding epidermis, with blister formation, rupture and gangrenous area. The eschar sloughs, and a superficial ulcer forms and heals slowly.

TREATMENT

About sixty preparations have been used in the treatment of arachnidism. Alcohol seems to be contraindicated, and fatal results have been reported from this agent.¹¹ Strychnine used to be given, and sedatives seemed the most rational treatment in former years. Intravenous magnesium sulfate until symptoms of spider poisoning have disappeared has long been recommended and seemed rational in cases in which hypertension was a prominent factor. Frawley and Ginsburg¹¹ had good results with magnesium sulfate in 11 cases, with freedom from symptoms in twenty-four hours. Hypertonic glucose has been used with varying results.¹² Morphine sulfate in heavy dosages has frequently been relied upon for relief by some physicians. The results of Gray's¹⁷ observations with convalescent serum seem to bear out the suggestion that antivenin is developed by the patient recovering from the bite of the black-widow spider. It is reasonable to suppose that it will prevent symptoms or cure spider-bite poisoning. Antivenin (*L. mactans*) is listed in *New and Non-Official Remedies*. It is standardized on the basis of its ability to neutralize the venom of the black-widow spider when the two are injected simultaneously in mice. Bell and Boone¹⁸ reported a single case in 1945 in which they regarded neostigmine methyl sulfate as an apparent specific treatment for arachnidism. This article stimulated much adverse comment from other observers, since much time and many other remedies had been given before neostigmine methyl sulfate therapy was instituted. It remained for Gilbert and Stewart¹⁹ to propose calcium salts as a very effective method of therapy. They reviewed previous therapeutic measures in the treatment of arachnidism and presented 5 cases in which intravenous solution of 10 per cent calcium gluconate gave instant and prolonged relief of pain and also produced relaxation of muscular spasm. The intramuscular route was recommended in children, with almost immediate relief. Calcium lactate was ineffective orally, probably because of its incomplete and slow absorption. Calcium chloride is not recommended because of its possible necrotic action on tissues. In the series reported in this article intravenous calcium gluconate was found to give immediate and prolonged relief of muscle spasm and pain in all cases, and it is believed that this is the best available therapy in conjunction with other supportive measures. Others have remarked on the relief given by frequent hot baths.^{2, 10} In Russia hot baths are often used in the treatment

of spider bite due to the "Karakurt," a closely allied species Finlayson²⁰ believes that tetanus antitoxin should be used in all cases

SUMMARY

Arachnidism, a definite clinical entity in medicine, is reviewed, and 6 cases successfully treated with intravenous injection of calcium gluconate are discussed

Arachnidism should be considered in indigenous areas in the differential diagnosis of the acute surgical abdomen. It may simulate appendicitis, perforated viscus, peritonitis or any other acute surgical emergency

The syndrome following the bite of *Latrodectus mactans* may give symptoms referable to many systems of the body. Nervous, cardiac, renal, pulmonary and cutaneous manifestations may be present

Burning of the soles of the feet may be pathognomonic in arachnidism

One should be familiar with the clinical picture so that proper diagnosis is made and proper therapy instituted with avoidance of unnecessary surgical operations

PERFORATION OF INFARCTED INTERVENTRICULAR SEPTUM, WITH PARTIAL HEART BLOCK*

LIEUTENANT (J G) RALPH VERNON FORD (MC), U S N †

BOSTON

THIS is the report of an acquired interventricular defect that developed at the site of an infarct high in the septum and was associated with partial heart block and a systolic murmur. In previous comprehensive surveys in 1934 by Sager¹ and in 1943 by Weber² a total of 35 cases of interventricular septal perforations due to infarction were collected. Since that time, 18 additional cases have been reported. Prior to the case reported below there were reports of only 2 cases of infarcted septal perforations with clinically detected conduction disturbances of the heart.

The purpose of this paper is to present a case of perforated infarct of the interventricular septum, to comment on the pathogenesis of the associated conduction disturbance and to review the relevant literature.

CASE REPORT

A 72-year-old woman was admitted to the hospital because of semiconsciousness of 4 hours' duration. Ten years pre-

viously she had suffered an attack of "acute" indigestion associated with substernal pain and dyspnea. Since then there had been no recurrence of these symptoms although she had noticed swelling of the ankles for the past few months. On the day before admission she suddenly felt weak and vomited, and was forced to return to bed. On the morning of admission she again vomited and returned to bed, and was found several minutes later in a semiconscious state. She was in obvious respiratory distress for the first time. There had been no chest pain.

Physical examination revealed a thin, dehydrated, semiconscious, orthopedic woman. The skin was cold, damp and cyanotic. Examination of the heart showed the rate to be 54 beats per minute, with frequent irregular beats and enlargement to the left and right. A loud systolic murmur was heard at the apex, but no thrill was felt. The liver was slightly enlarged.

The blood pressure was 76/40.

An electrocardiogram (Fig 1) showed second degree heart block, an abnormal form of the ventricular complex (depressed ST segments in Lead I, elevated ST segments in Leads 2 and 3 and late inversion of the T wave in Lead 3), elevated ST segments in Lead aVF, and depressed ST segments in Lead VI-5 with unusually high T waves in Lead V3,4. These findings were interpreted as evidence of acute posteroseptal myocardial infarction.

The patient failed to improve and died quietly 5 hours after admission.

On post-mortem examination the most striking findings were in the heart. The coronary arteries were markedly calcified. The left coronary artery was widely patent though markedly sclerotic. The right coronary artery at a point

3 cm from its origin was obstructed for a distance of 0.5 cm by a dark-purple, moist mass. Microscopical examination revealed that this was not a thrombus but rather an acute exudative reaction within an intima that was the seat of

be noted that except at the point of perforation of the infarcted septum there was a narrow zone of noninfarcted myocardium immediately beneath the endocardium and beneath the crest of the muscular portion of the septum. Microscopical examination showed changes corresponding to those of myocardial infarction of 48 to 72 hours' duration according to the criteria of Mallory and White.³

DISCUSSION

In general, infarction involving the superior portion of the interventricular septum is likely to produce disturbances of conduction such as auriculo-ventricular block whereas infarction of the lower apical portion of the septum is more apt to perforate, causing an acquired interventricular

ventricular septum to a point 3 cm distally, the myocardium was infarcted. Through the middle of this infarcted area there was a fistulous tract, 1 cm in diameter, lined by fibrous material connecting the two ventricles (Fig 3). It is to

FIGURE 3 *Gross Cross-Section of the Heart near the Base, Showing Perforation through an Infarction of the Posterior Portion of the Interventricular Septum*

septal defect and, characteristically, Roger's murmur. In the case reported above, the perforation of an infarct in the posterosuperior portion of the interventricular septum, with electrocardiographic evidence of second-degree heart block, comprised a situation of unusual rarity and interest. It was noted that the infarction extended to within 1 mm of the crest of the muscular portion of the septum upon which, according to tradition, the auriculo-ventricular bundle of His rests. After coursing further forward, the bundle of His is said to divide into its two main branches, which then extend downward beneath the endocardium of the muscular septum to the apex. Thus, the location of the infarction and perforation in this case was such as to avoid the bundle branches, but may have involved the main bundle.

REVIEW OF THE LITERATURE

The cases reported by Sager¹ and Weber,² as well as others, were confirmed by post-mortem examination.

In a series of 25,000 autopsies, Edmondson and Hoxie⁴ found 72 cases of cardiac rupture (13 of which were septal) in 865 hearts with recent infarcts.

Wood and Livezev⁵ described the case of a forty-four-year-old man who lived for four years and ten

months after septal perforation following myocardial infarction. This is the longest survival yet reported. It was the sixth case of a septal perforation following a posterior myocardial infarction and only the second case with the associated electrocardiographic finding of right-bundle-branch block.

A case from a clinicopathological conference was presented by Lober and Hertzog⁶ in which an antemortem diagnosis of septal perforation was made.

The patient of Master and Russell⁷ was a forty-seven-year-old man with an acute anterior and posterior myocardial infarction confirmed by the electrocardiogram who developed signs of septal perforation on the third day and died on the eleventh day. Autopsy confirmed these diagnoses and revealed a perforation in the inferior portion of the septum.

Lian's⁸ case of posteroseptal perforation was diagnosed before death and was a remarkable combination of the typical clinical syndrome with electrocardiographic findings of acute posterior myocardial infarction. Analysis of expired air showed a low carbon dioxide content.

Diaz-Rivera and Miller⁹ described 5 cases of cardiac rupture. Only 1 was septal, and it was recognized before death. The patient was a sixty-five-year-old man with typical infarction clinically. On the second day a systolic murmur developed at the cardiac apex and in the third interspace to the left of the sternum. The electrocardiogram showed right-axis deviation, multiple premature contractions and changes consistent with an acute

myocardial infarction. Autopsy confirmed the diagnosis of septal perforation.

SUMMARY

A case of posteroseptal myocardial infarction in which rupture of the septum developed just beneath the "membranous septum" is reported. Electrocardiographic examination shortly before death showed second-degree heart block as well as the characteristic changes of posterior infarction. A loud systolic murmur was heard at the apex, but the patient was not observed long enough for the time of development of the murmur to be established.

PREMEDICATION IN ANESTHESIA

Unusual Experience with Concurrent Administration of Barbiturate and Pantopon

JAMES C. McCANN, M.D., Ph.D. (SURG)*

WORCESTER, MASSACHUSETTS

THE administration of an anesthetic may be smoothly supplemented or seriously distorted by the use of premedication. The importance of premedication in anesthesia manifests itself in two directions: it has a quieting sedative effect, which renders the patient more amenable to induction, reduces the amount of anesthesia needed for maintenance and prolongs the period of calm following operation, and it manifests side effects, particularly on respiratory activity, which may seriously disrupt the course of anesthesia. The action of the premedicaments in these respects is directly related to tissue susceptibility or idiosyncrasy on the part of the patient.

This report is a consequence of interest in the barbiturates as anesthetic agents that dates back to the use of sodium amytal over fifteen years ago when a report on the use of that agent was published. In that report attention was called particularly to the undesirable side effect of the drug on the respiratory system—pulmonary edema. Four years ago major surgical procedures were undertaken with sodium pentothal administered intravenously as the principal anesthetic agent. A method of supplementing pentothal with trans-incisional novocain nerve block was worked out that established pentothal as a satisfactory anesthetic agent for intravenous injection. This statement is made despite the fact that the use of the agent was undertaken with a critical rather than a favorable bias after the unsatisfactory experience with sodium amytal.

The problem of premedication soon assumed basic importance. Pentothal is directly a depressant of the respiratory center, as are most other anesthetic agents. The depressing action is most marked on the expiratory side of respiration. Pentothal particularly suppresses the reflex stimulation of the expiratory phase of respiration, which results from neurogenic impulses originating in the field of operative trauma. In this respect it tends to restore the reflexly distorted inspiratory-expiratory time ratio from an abnormal 1:4 or 1:6 ratio to a more normal 1:1 ratio. However, pentothal does not exhibit a distinctive effect of both cyclopropane and ether in deeper planes of anesthesia—namely, paradoxical respiration. This effect depends on pharmacologic dissociation of the intercostal and diaphragmatic components of respiration, whereby deep inhalation anesthesia paralyzes the intercostal

component long before there is paralysis of the diaphragmatic component. Pentothal anesthesia, in contrast, when carried too deeply produces concurrent intercostal and diaphragmatic paralysis with the sudden development of apnea. In the light of such pharmacologic facts, the use of premedicating drugs that initially depress the respiratory center calls for careful weighing of their value against the increased depression of the respiratory center by the anesthetic agent.

My experience with intravenous injection of pentothal and trans-incisional nerve block has persuaded me that cautious but effective premedication is a major factor in the successful and satisfactory use of pentothal anesthesia intravenously. The patients are calm, often very drowsy, neurogenic impulses, which reflexly stimulate the respiratory center and influence the rate of utilization of pentothal, are reduced in intensity, induction is more even and quick than it is in the absence of premedication, and the maintenance period requires lesser amounts of pentothal. In view of these apparent facts I have been alert to the problem of synergistic or additive action of opium derivatives used in conjunction with intravenous administration of pentothal anesthesia. The following unusual case, therefore, was considered sufficiently illuminating on this point to merit reporting.

CASE REPORT

A 61-year-old man was referred for surgical treatment of a partially obstructing duodenal ulcer which had not responded to medical treatment. Operation had been planned under continuous pentothal and ether anesthesia with anterior splanchnic block. The patient was given the usual premedication therapy—0.2 gm (3 gr) of nembutal by mouth the night before operation, 0.1 gm (1½ gr) of nembutal by mouth the morning of the operation, and 0.02 gm (½ gr) of pantopon with 0.0006 gm (1/100 gr) of atropine subcutaneously ½ hour before removal to the operating room. The operation was postponed after premedication had been given because of a reported temperature of 101°F due to an upper respiratory infection. It was later noted that the patient became profoundly drowsy after the medication, with a respiratory rate of less than 10 per minute. After several days, when the cold was better, a posterior gastroenterostomy was performed under the following unusual circumstances. The premedication mentioned above was repeated. Intravenous administration of pentothal had just been started and only 2 cc. of a 1 per cent solution (½ of a grain, a negligible quantity) administered when the anesthetist noted that the respirations were only 5 per minute. The pentothal anesthesia was immediately stopped and no further anesthesia of any kind was administered. The respiratory effort although infrequent was of full amplitude and vigor, and kept the patient in good color. The patient was in deep sleep. The incision was attempted and was continued through all layers of the abdominal wall until the peritoneum was opened. The patient slept soundly with no motor re-

*Surgeon St. Vincent's Hospital.

sponse or objective sign of discomfort from the incision. There was no reflex stimulation of the respiratory center from neurogenic impulses generated by surgical trauma, even from manipulation of the peritoneum such as traction on the stomach. The rectus muscles were relaxed by transincisional novocain block of the intercostal nerves in the sheath. This produced no sensory anesthesia. The anterior splanchnic block was not made, on purpose, the full extent of this unusual drug action being watched for. Intermittent administration of oxygen was carried out. The respirations continued at 5 per minute and were of full amplitude and force on the inspiratory side. Expiration was passive, with no reflex activation of the lateral abdominal muscles as accessory muscles of respiration. There was a long pause, resulting from total respiratory inactivity between expiration and inspiration lasting for about 10 seconds. As the patient's color and condition remained excellent the operation was continued, and a posterior gastroenterostomy performed in a perfectly quiet abdomen.

There was never the slightest evidence of discomfort on the part of the patient. He simply slumbered on. After completion of the anastomosis the abdomen was closed in a routine fashion without the slightest grimace or evidence of discomfort. While the skin was being sutured the patient was shaken sufficiently to arouse him slightly. He was asked whether he had any pain. He shook his head. From then on he made a slight grimace each time the needle was passed through the skin, but nothing else was observed. At the completion of the operation the patient was returned to bed and placed in an oxygen tent. His respirations gradually increased in frequency until they reached 12 per minute by 3 p.m. He became extremely restive at that time and was given 8 mg ($\frac{1}{8}$ gr) of morphine, which immediately depressed his respirations to 10 per minute. He made an easy recovery, being out of bed the following day. He returned home on the 14th day.

Additional observations made on the operating table and during convalescence enhance the interest in but fail to explain this unusual experience. During the course of the operation the patient was rebreathed with oxygen and carbon dioxide (95 and 5 per cent) with an increase in the volume but not in the rate of respiration. He was subsequently rebreathed with pure carbon dioxide for a few seconds, the volume of respiration again increasing and the rate rising from 5 up to 7 per minute. When the pure carbon dioxide was discontinued the rate of respiration immediately dropped back to 5 per minute. The patient was given irritating inhalations of ether fumes to determine if this stimulation would increase the rate of respiration, but it failed to do so. He was given an injection of metrazol and 0.4 mg (1/150 gr) of atropine without stimulating effect on the center, a repeated intravenous injection of metrazol and 0.4 mg of atropine was given, but there was not the slightest increase in either the rate or the depth of respiration, even though the injections stimulated the cerebrum sufficiently to arouse the patient slightly.

During the period of convalescence an attempt to place responsibility for this effect was made by fractionation of the premedication. On one occasion 0.2 gm of nembutal was given at night and 0.1 gm repeated in the morning. The pantopon was withheld. There was no effect other than that of providing a good night's sleep. While the patient was resting in bed the respirations were 16 per minute, and he was quite awake. He was up and about shortly. On another occasion 0.02 gm of pantopon was given in the morning with full precaution to avoid any administration of nembutal the night before. This drug alone had no apparent effect. The patient lay in bed fully awake, with respirations of 16 per minute. On a third occasion the entire premedication routine, with the exception of atropine and pantopon, was repeated with careful watch of the sequence of events. He lay quietly in bed, with respirations normal, awake and complaining because his breakfast was held up. He then received the hypodermic injection of 0.02 gm of pantopon. Over a period of 10 minutes he gradually passed into a state of profound sleep from which he was aroused with difficulty. His respirations dropped steadily during this period to the depressed point of 9 inspirations per minute, and they remained at that level for about 1 hour. They then gradually returned to normal, and the patient was up and about in 4 hours, looking for his breakfast.

DISCUSSION

This experience was apparently a manifestation of unusual combined action by ordinary doses of nembutal and pantopon administered to an adult normal in all respects except for some loss of weight. On the basis of either synergism or additive effect an abnormal suppression of the usual controls of inspiration occurred. On separate occasions combined medication dropped respirations to 5 and 9 per minute. The failure of response to carbon dioxide places the effect on a neurogenic rather than a chemical basis. Failure of response to the pharmacologic stimulation of atropine and the analeptic metrazol indicated the profound depression of the nervous elements in the respiratory center. The absence of reflex neurogenic stimulation from the trauma of surgery was impressive. The phenomena were not in line with the usual action of barbiturates as noted in the administration of intravenous pentothal anesthesia. Barbiturate action tends to normalize the distorted respiration caused reflexly by neurogenic impulses originating in the operative zone. These pain impulses convert expiration from a passive to an active phase characterized by forceful expiratory contractions of the lateral abdominal muscles as accessory muscles of respiration. The expiratory phase of respiration is prolonged by these reflexes, with a distortion of the inspiratory-expiratory time ratio from the normal of 1:1 to an abnormal ratio of 1:4 or 1:6. Barbiturates (pentothal) act on the expiratory component, suppressing the sharp reflex activation of this expiratory phase until the ratio is restored to the quiet, normal 1:1 ratio of the resting state. Beyond this point, there is a reduction in the amplitude and force of respiration by the barbiturates, but usually no alteration of the rate even up to the point of complete apnea.

In contrast with the usual barbiturate action on the expiratory side this experience was one of ineffective inspiratory stimuli that failed to act on the respiratory center in a normal rhythmic fashion. There was a full normal inspiratory effort, followed by passive expiration. There followed a long pause for a resting period of nine or ten seconds. Predicating inspiratory act on the Hering-Breuer reflex, it seems that the threshold for these reflexes had been so elevated by the combined effect of the drugs that it required a summation of stimuli for a period of several seconds finally to achieve sufficient intensity to break over the elevated level of the threshold and create an effective inspiratory impulse. This is more in line with the action of the opiates, so that responsibility for this picture may be ascribed more to the pantopon than the barbiturates.

Undoubtedly, the reduced metabolism at sixty-one years of age contributed to this occurrence. As phenomenal as the depressing effect of these

drugs on the respiratory center was the interruption of the pain pathways to consciousness as a result of which a major operation on the upper abdomen was easily and comfortably performed without benefit of any other anesthetic agent. Administered separately, the drugs displayed no unusual effect. Administered concurrently, they exhibited a remarkable enhancement of pharmacologic effect in three directions: profound sleep, suggesting maximal barbiturate action on the cortex, interruption of pain sensations, suggesting pantopon and possibly some barbiturate action on the thalamus, and depression of respiration on the inspiratory side, suggesting enhanced pantopon action on the inspiratory neurons of the respiratory center — both intercostal and diaphragmatic.

SUMMARY

An unusual case of a gastroenterostomy performed under the effects of preanesthetic medication alone is reported.

Premedication consisted of 0.2 gm of nembutal, given during the night before operation, 0.1 gm of nembutal, administered on the morning of operation, 0.02 gm of pantopon, and 0.0006 gm of atropine, given half an hour before removal to the operating room.

Besides profound sleep and the absence of reflex response to pain, there was depression of respirations to 5 per minute. The respiratory center could not be stimulated by carbon dioxide in ordinary

concentrations or by atropine, metrazol or irritating ether fumes, it responded feebly to pure carbon dioxide. It did not respond reflexly to the neurogenic stimuli of surgical traumatic origin.

Controlled postoperative observations showed that neither nembutal nor pantopon used separately in the same doses had any comparable action. In combination this profound effect, either synergistic or additive, was elicited on three separate occasions.

The possibility of such potent mutual enhancement of pharmacologic effect by barbiturate and opium derivatives administered concurrently prior to anesthesia should be fully recognized even though rarely encountered. This experience also emphasizes the care that should be exercised in the administration of narcotics postoperatively to patients who have received pentothal sodium intravenously during anesthesia.

CLINICAL NOTE

AN OBSERVATION OF ANTITOXIN TITERS AFTER BOOSTER DOSES OF TETANUS TOXOID*

H J BANTON, M.D.,† AND PAULINE A MILLER, M.S.‡

BOSTON

THE efficacy of tetanus toxoid as an agent for the prevention of clinical tetanus has been well established.^{1,2} The procedure now most widely employed is to give a basic immunizing course followed by a booster dose at least six months later. Another booster dose is then given in any emergency after an injury that might lead to tetanus infection.

The protection afforded is unquestionably based in large part upon the residual titer of antitoxin persisting after primary immunization and greatly

augmented by routine booster doses. Much stress has also been laid on the capacity of an emergency dose, given after injury, to induce a rapid rise in serum and tissue antitoxin levels. Little information is available, however, regarding the rate at which this rise occurs in human beings. An opportunity arose of plotting the response to a booster dose in 5 members of the staff of the Division of Biologic Laboratories of the Massachusetts Department of Public Health, who received 0.5 cc doses of fluid tetanus toxoid§ subcutaneously in the course of a routine immunization clinic in the Division. All five had previously been immunized with fluid tetanus toxoid either in the Division or while on military duty. The interval in each case since the last injection is shown in Table 1 below. Test bleedings were taken for determination of antitoxin titer just prior to this inoculation, and were repeated from the fourth to the tenth day, inclusive.

This study was undertaken as a result of the joint interest, extending over the past six years, of the Division of Biologic Laboratories and the Department of Bacteriology and Immunology of Harvard Medical School in the preparation, properties and use of tetanus toxoid, and is reported by those re-

The person with the highest residual titer had received toxoid the most recently, and conversely the lowest residual titer was coupled with the longest interval

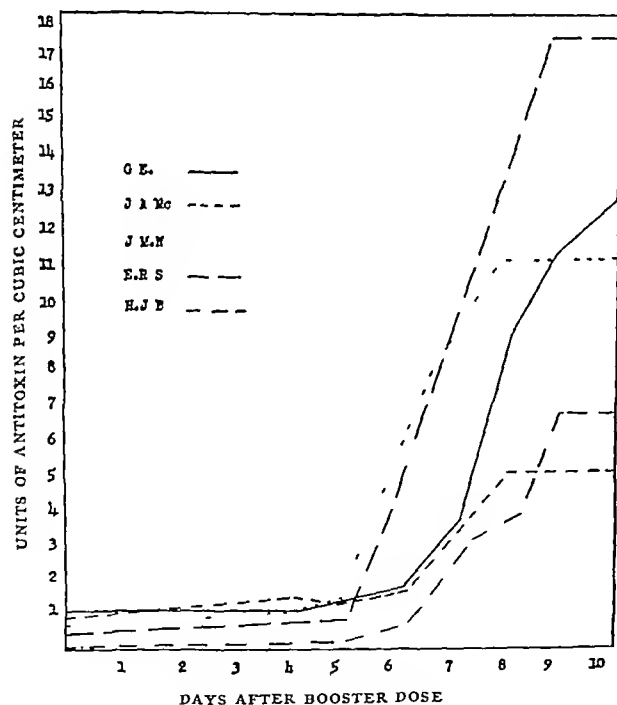

FIGURE 1 Response to Booster Dose of Tetanus Toxoid

None of the titers started to rise before the fifth day, and all were leveled off or appreciably checked by the tenth day. This lag in rise compares with other findings such as those of Gold,³ who found

Since many fatal cases of tetanus terminate within four days of the date of injury, it is apparent from this small number of data that dependence on the booster dose alone after injury may not assure sufficient protection. The residual antitoxin titer resulting from prior immunization may be of greater importance. For adequate protection against tetanus, therefore, it appears that patients should receive periodic maintenance doses as well as the primary immunization, and then receive emergency injections when injured. No set interval for such periodic doses has been established. Evidence suggests that definite protection may persist for as much as five years.^{1,4} In this study the residual titer of 1 subject (H J B) at five years and eight months (Table 1) may have been below the level of adequate protection. Reason suggests, therefore, that periodic booster doses be given for maintenance purposes at intervals of three to four years.

The recent suggestion of a Massachusetts practitioner that physicians in the Commonwealth follow up former servicemen and servicewomen among their patients, and persuade them to have periodic tetanus booster doses, is an excellent one. If this is done a large group of the population can easily be kept immune to tetanus.

MEDICAL PROGRESS

SURGICAL APPROACH TO CONGENITAL CARDIOVASCULAR DEFECTS*

I M ESSRIG, M D †

NEW ORLEANS, LOUISIANA

PROGRESS in the treatment of congenital cardiovascular defects has been so extensive and spectacular during the past decade that considerable interest has been focused on the entire field of cardiac surgery. In attempting a survey of the surgical approach to the special subdivision of congenital cardiac anomalies, it seems desirable to make a brief review of the older — as well as the new — aspects of general cardiac surgery to evaluate the recent advances more clearly.

HISTORICAL APPROACH

The story of the surgery of the heart is one of the most fascinating in all the annals of medicine, although its development has been relatively slow. This was appreciated in the early days of this century, for Sherman¹ remarked in the annual surgical oration before the American Medical Association in 1902, "The road to the heart is only two or three centimeters in a direct line, but it has taken surgery nearly 2400 years to travel it." (The chest was first opened for empyema in the Hippocratic era.)

Infection

Acute suppurative disease was the first to receive attention,² although many years passed before the suggestions of the pathologists were acted upon by their surgical colleagues. Exactly three hundred years ago Jean Riolan,³ though a staunch Galenist, and a violent opposer of Harvey's new teachings,⁴ advised trephining of the sternum for drainage of the pericardium. A full century passed, deSenac⁵ described pericarditis, recommending drainage for its treatment with the opening in the chest to be made to the left of the sternum in an intercostal space. Still nothing was achieved, and after another half century Desault⁶ and, a few years later, Larry⁷ attempted the procedure, but unfortunately in both instances the diagnosis was in error. Romero,⁸ in Spain, was finally successful in 1819, opening the pericardium for effusion in 3 cases, with 2 patients surviving.

Despite repetition in various countries, the operation did not gain favor, and Billroth⁹ coldly stated, "Parentesis pericardii is a prostitution of the surgical art — possessing more interest for anat-

mists than for surgeons." With this lack of encouragement it took surgeons nearly another century to pass from the pericardium to the epicardium across a space that is such only potentially.

Trauma

Louis Rehn,¹⁰ of Frankfurt, was the first to suture successfully a wound of the heart, and he also was the first to perform decortication for adhesive pericarditis. Moreover, he accomplished a great deal of clinical investigation, and appeared frequently before the profession to defend the infant specialty. For these reasons he might well be considered the father of cardiac surgery. How young this branch of surgery really is can be appreciated by the fact that Rehn died in 1930¹¹ at the age of eighty-one. Interestingly enough, it was in his city of Frankfurt that William Harvey,¹² the discoverer of the circulation, first published (1628) his revolutionary studies on the motion of the heart and blood. To be sure, it was long before Rehn's time that Morgagni¹³ had stressed the danger of compression of the heart from hemorrhage into the pericardial sac, which Rose¹⁴ in 1884 termed "Hertz tamponade." And Block,¹⁵ of Copenhagen, confirmed Morgagni's observations that cardiac wounds were well tolerated and boldly proposed the suture of such wounds as a surgical remedy, having successfully demonstrated its feasibility on rabbits in 1882. Nevertheless, general response was not enthusiastic. Billroth,¹⁶ in the following year — still cold — wrote, "The surgeon who should attempt to suture a wound of the heart would lose the respect of his colleagues." In 1896 Stephen Paget,¹⁷ son of the famous Sir James Paget, stated, in the first work devoted to this subject in English, "Surgery of the heart has probably reached the limits set by Nature to all surgery — no new method and no new discovery can overcome the natural difficulties that attend a wound of the heart."

As if in rebuttal, Rehn,¹⁰ that very year, reported the case of a twenty-two-year-old man with an actively bleeding wound of the right ventricle, which he closed with silk sutures, the patient made an uneventful recovery. This was all the spark that was needed.¹⁸ Within six years, 34 additional operations had been reported. These were reviewed by Sherman¹ in an article that also described his investigations in the use of stay sutures in the ventricle as a method of holding the heart. In 1920 Sir

Charles Ballance¹⁹ gave an excellent historical review of the surgical treatment of infectious and traumatic aspects of cardiac disease

Acquired Disease

Billroth²⁰ made another gloomy statement, around 1875, that "those most deeply concerned in the practice of internal medicine make plans for the boldest operations" If the surgical aspect of acquired cardiac disease is divided into three categories—valvular disease, adhesive pericardial disease and myocardial disease—operative intervention in each one was initiated by a bold, clear-thinking, prophetic clinician, each an internist who was to make significant contributions in other fields

Sir Thomas Lauder Brunton,²¹ the discoverer of amyl nitrite, startled the medical profession in 1902 with the suggestion that operative intervention be employed for mitral stenosis, but was uncertain whether the valve should be approached through the auricles or through the ventricles¹ Vigorous letters, pro and con, but mostly con,²² appeared in the English medical journals Nevertheless, American workers were intrigued by the idea, and pioneer investigative work was launched by W G MacCallum,²³ Harvey Cushing,²⁴ B M Bernheim²⁵ and the late Elliott C Cutler²⁶ Successful operations were reported by Tuffier²⁷ for aortic stenosis, and by Souttar²⁸ for mitral stenosis, both employing digital dilatation of the diseased valve Cutler, Levine and Beck²⁹⁻³⁰ utilized a tenotome knife in 3 cases and then an ingenious instrument—a cardio-valvulotome³¹—to cut stenotic mitral valves in 4 more cases Unfortunately, only the first patient survived Allen and Graham³²⁻³³ perfected a cardioscope with which they could visualize the interior of the heart, but their clinical attempt to use it, as well as Pribram's³⁴ effort, met with failure These experiences resulted in a quietus in surgical intervention for valvular disease until the present time

Brauer,³⁵ who later established the modern concept of thoracoplasty, suggested the procedure of cardiolysis for adhesive pericarditis His proposal gained favor much more quickly than that of Delorme,³⁶ who several years earlier, after careful study of cadavers, had advocated decortication of the heart (He had previously introduced decortication of the lung) Delorme pleaded in vain before various clinical societies in Paris for performance of his operation,³⁷ but it was not until Rehn, doubtful, but still a trail-blazer, performed a decortication for the severer internal form of adhesive disease, concretio pericardii, that the procedure was carried out In 1920, 4 cases were reported with good initial results³⁸

Heberden³⁹ had described what he called "Pectoris Dolor," in 1772, and his contemporary, Jenner,⁴⁰ of vaccination fame, understood its underlying cause Those so afflicted had to suffer almost

another one hundred years before any effective therapy appeared, when Brunton,⁴¹ just a year out of medical school, discovered that amyl nitrite could produce dramatic relief in anginal attacks François-Franck,⁴² known for his sign in patent ductus arteriosus and for cerebral localization, after twenty years of patient research, demonstrated that the sympathetic nervous system has a centripetal function, and that sympathetic ganglions are able to function as reflex centers⁴³ He showed that aortic pain was carried by cervicothoracic sympathetic nerves and in 1899 suggested their resection in angina pectoris An interval of seventeen years elapsed before Jonnesco⁴⁴ first put these ideas to test Daniélopou⁴⁵ and Mandl⁴⁶ also attempted to relieve pain by resection or block of the sympathetic pathways

The next attempt was to reduce the work of the heart by total thyroidectomy,⁴⁷ but this procedure has generally been abandoned⁴⁸

Beck⁴⁹⁻⁵¹ has been the most diligent worker in investigating means to improve the blood supply to the heart He has tried, among other things: chemical irritation of the pericardium—Dakin's solution, silver nitrate, hypertonic saline solution and so forth, foreign-body irritation—gum acacia, horse serum, kaolin and bone powder, myocardial grafts—pericardial fat, pedicle grafts of skeletal muscle from the chest wall, the omentopexy of O'Shaughnessy⁵², and arteriovenous anastomosis (discussed below)

Congenital Defects

The chapter on congenital defects begins with J C Munro,⁵³ who proposed ligation of the patent ductus arteriosus at a meeting of the Philadelphia Academy of Surgery in 1907 This illustrious man was far ahead of his time, although Doyen,⁵⁴ in 1913, unsuccessfully attempted to overcome a congenital pulmonic stenosis with the use of a tenotome In 1937 Strieder⁵⁵ was also unsuccessful in operating upon a patient with patent ductus arteriosus and superimposed subacute bacterial endarteritis

Matas,⁵⁶ in his extensive treatise on cardiovascular surgery, did not even mention congenital defects, and only a decade ago, Levine⁵⁷ stated in his excellent text, "There is no known treatment for congenital heart disease" With timing reminiscent of Rehn, Robert Gross⁵⁸ introduced the present period with the first successful operation for congenital cardiovascular disease, ligating a patent ductus arteriosus in a seven-year-old girl in August, 1938 As might be suspected, one of Billroth's "internists," the child's pediatrician, J P Hubbard, had urged the performance of this procedure

Other leaders of the present decade are Crafoord,⁵⁹ of Stockholm, who first operated for coarctation of the aorta in October, 1944, and Blalock,⁶⁰ who devised the procedure for congenital pulmonary

enosis and first performed this operation in November, 1944. The list of cardiac firsts for this period is so full and varied that objective appraisal is difficult, to say the least.

Two women played a prominent role in laying the spadework for the surgical approach to congenital cardiovascular defects: one, a pediatrician, Helen Taussig, and the other a pathologist, Maude Abbott. Taussig made the suggestion to Blalock that an operation devised to increase the flow of blood to the lungs in cases of pulmonic stenosis would improve the condition of the so-called "blue baby."⁶¹ Her recent monograph on congenital malformations of the heart is a classic.⁶² After encouragement by William Osler, Maude Abbott⁶³ began a collective series of congenital heart lesions, and in 1936 published her atlas of 1000 cases, a milestone in cardiac history. Her efforts, more than anyone else's, provided the stimulus toward present-day interest in the treatment of cardiac anomalies. She devised a clinical classification for congenital heart disease in which patients are divided into three groups.⁶⁴

Group I comprises those without abnormal communications between the right and the left sides of the heart — thus, cyanosis is not a part of the picture. Included are such congenital malformations as simple dextrocardia, pericardial anomalies, pure aortic or mitral stenosis and coarctation of the aorta.

Group II embraces patients with arteriovenous shunt, in whom arterial blood enters the pulmonary circulation. Cyanosis is usually not observed. There is, however, possible transient reversal of flow, with cyanosis. Contained in this group are defects of the interauricular or interventricular septums and patent ductus arteriosus.

Group III includes patients in whom cyanosis is a prominent feature. Among the many causes are defects of the interventricular septum with dextro-position of the aorta, tricuspid stenosis and atresia, transposition of the great vessels, Eisenmenger's complex and the tetralogy of Fallot.

It is exceedingly difficult to estimate the incidence of these major groups or of their components, because of the multiplicity of many defects, as well as the variations that occur with a single lesion, for example, an interauricular defect may be high, low, large, small or primary, or may represent persistence of the foramen ovale and so forth. Nevertheless, it is desirable to have some idea of the approximate range of occurrence, as an aid in orientation, if for no other reason. Since no estimate was noted in the literature surveyed, a list of major defects, admittedly not exact, was compiled on the basis of an analysis of Abbott's cases (Table 1).

EMBRYOLOGIC APPROACH*

Before the conditions amenable to surgery are considered, it is of interest to note the major embryologic implications of congenital cardiac defects.

Developmental defects of the heart and great vessels are surprisingly few, considering that the mammalian embryo, having practically no yolk available as food, is dependent upon prompt establishment of relations with the maternal circulation. This entails the necessity of a precocious development of the vascular system of the embryo, for the maternal circulation remains confined within the uterine wall and the embryonic circulation must grow to it.⁶⁵

The heart of the human embryo begins to be formed during the third week of development. Dur-

TABLE 1 *Compilation of Major Defects*

DEFECT	INCIDENCE %
Acyanotic group (approximately 25 per cent)	
Coarctation of aorta	8
Anomalies of aortic arch	2
Aortic stenosis	2
Anomalies of semilunar cusps	3
Pericardial defects	3
Displacements of heart	2
Cyanotic tardive group (approximately 50 per cent)	
Patent ductus arteriosus	15
Defects of auricular septum	20
Defects of ventricular septum	17
Cyanotic group (approximately 25 per cent)	
Tetralogy of Fallot	12
Tricuspid atresia	1
Pure pulmonary stenosis	1
Transposition of great vessels	2
Eisenmenger's complex	5
Persistent truncus arteriosus	1
Complete septal defects (cor triloculare and biloculare)	1

ing the third and fourth weeks the primitive cardiac tube can be seen passing through the pericardial cavity and fixed to the pericardial wall only at its caudal venous entrance and cephalad arterial exit. Since it grows faster than the pericardial cavity, it is bent first in a loop and then in a fallen-S-shaped curve to stay within its boundaries. The proximal arterial end bulges forward and downward, whereas the atrial end pushes behind and above the ventricle. The blood leaves this primitive heart by way of the truncus arteriosus. Later, the truncus separates into aortic and pulmonary trunks. The basis of the partitioning of the heart into right and left sides is largely laid down during the second month of development.

The critical period in the human subject occurs between the fifth and the eighth week — that is, before the cardiac septums are fully formed and while the complex processes of torsion, involution, readjustment and fusion are taking place at the base of the heart, interruption of which is the source of most of the graver anomalies.

If development stops with the pre-septate tubular organ with ventricular bend to the right, the adult fish heart is seen. Similar conditions prevail in the amphibian heart, except that here subdivision into lateral chambers is suggested. Both are examples of cor biloculare.

*Patten's excellent new text *Human Embryology* was used as a guide for this section.

Further ontogenesis is reflected in the reptilian heart, the ordinary snapping turtle having two completely divided auricles, but only a common ventricle — cor triloculare

Meckel,⁶⁶ the "younger" of that famous family, noted in 1802 the curious manner in which graver cardiac anomalies mirror the hearts of the lower vertebrate orders. Von Rokitsansky⁶⁷ (1875) placed the origin of septal defects in the early weeks of embryonic life, while in 1905 Sir Arthur Keith⁶⁸ showed that persistence of the reptilian bulbus was the main etiologic factor in pulmonary stenosis. Spitzer,⁶⁹ in 1923, crystallized these investigations with his theory that arrest or delay of the clockwise torsion that normally takes place in the tubular heart between the fixed arterial outlet and venous inlet during the process of septation accounts for transposition of the great vessels, inverted ventricles and most of the other anomalies.

ETIOLOGIC APPROACH

The cause of malformations of the heart is not clear. Undoubtedly many factors may affect the development of the embryo, both intrinsic and extrinsic.

Intrinsic Factors

These factors are inherent in the male or female germ plasma prior to fertilization, owing to defects in genes transmitted by the laws of heredity. These defects occur because of the phenomenon of mutation — that is, the occurrence of a change in one of the genes that compose the chromosome thread, becoming reproduced in subsequent generations.

The production of such anomalies is in a sense the most characteristic thing about all living matter, being the property that most basically distinguishes living matter from nonliving and that has allowed protoplasm to develop, in its evolution, all the further peculiarities of the human organism.⁷⁰

Murphy⁷¹ has estimated the occurrence of live-born, malformed offspring to be 1 in 213 births. There is a better than 10 per cent chance that a subsequent pregnancy will eventuate in a malformed infant (1 in 8, or twenty-four times greater than the average incidence). The great influence of intrinsic factors is represented by the fact that Murphy found in families possessing two or more malformed children, the defect in the first-born malformed member duplicated in a subsequent malformed sibling in nearly half the cases. This incidence of 50 per cent also was true of duplication of malformation in distant relatives.

The actual incidence of congenital cardiovascular defects at New Orleans Charity Hospital between 1927-1936 was 1.08 per cent.⁷²

Extrinsic Factors

Therapeutic amounts of radium or roentgen irradiation of the human pelvis during pregnancy are

extremely likely to injure the embryo.⁷³ This injury may be due to breakage or rearrangement of chromosome parts, so-called "translocation," which has been shown to occur when mature germ cells are subjected to radiation. Muller,^{74, 75} recent Nobel prize winner, has estimated that the extrinsic factor — irradiation — produces gene mutations (thus becoming an inherited or intrinsic factor) about one hundred times greater than the frequency of spontaneous mutation. It has also been established that the frequency of induced mutation will be proportional to the total dose of radiation received over an unlimited period — that is, the total amount absorbed. Because most such mutations are recessive many generations may pass before the eventual lethality of the defect appears or "shows." On this basis Muller has calculated, for example, that each atomic bomb falling in a highly populous area would probably kill more people scattered throughout future generations than those killed in the generation immediately affected.

Other mutagenic agents are mustard gas,⁷⁶ carcinogenic agents^{78, 79} and perhaps even cosmic radiation.⁸⁰ The importance of mutational prophyllaxis as related to congenital defects is obvious.

Virus infection has likewise been implicated as a major extrinsic factor.⁸¹ Gregg⁸² and Swan⁸³ have definitely shown that German measles in the first two months of pregnancy is associated with an extremely high incidence of congenital cataracts and congenital malformations of the heart, if maternal rubella occurs in the third month of pregnancy there is still a high probability that such defects will occur. After the third month the cardiovascular system is practically completely formed, and there is apparently slight liability of injury to the fetus.

Vitamin deficiency during pregnancy has also been shown to be a factor.⁸⁴

DIAGNOSTIC APPROACH

Taussig⁸⁵ has emphasized the differences in diagnosis of congenital heart disease of infants as compared to adults. The same methods of diagnosis that have proved useful in adult cardiac abnormalities were also applied to infants. This is a serious error. Whereas special characteristics of murmur are of great diagnostic aid in adults, in infancy, although the appearance of a murmur may suggest an abnormality, the heart is too small, the blood pressure too low, and the chest wall too thin for the murmur to be of specific diagnostic aid. The existence of a congenital malformation of the heart is suggested in infants by the detection of unusual murmurs and thrills, by the presence of cyanosis with or without clubbing of the fingers and by alteration in the size or shape or position of the heart.

Accurate diagnosis is frequently made possible by the information derived from physical and x-ray examination, and fluoroscopy. Additional important

aids to diagnosis are angiocardiology — that is, contrast visualization of the heart and great vessels with opaque substances — and physiologic studies of intracardiac pressures, oxygen saturations and calculations of cardiac blood flow. Such measurements are obtained by catheterization of the right side of the heart, including the right auricle and the right ventricle and, when possible, the pulmonary artery. The chief criteria for diagnosis are alterations in oxygen content in one or another of these chambers and alterations in pressures.

Cournand and his associates^{55, 56} have shown that by means of the Fick principle⁵⁷ the volume of flow through these chambers may be estimated. The output is calculated from the difference between the oxygen content of the venous blood and that of the arterial blood, and the total oxygen consumption. It is evident that if the quantity of oxygen that a unit of blood delivers to the tissues (or takes up from the lungs) is known, together with the total quantity of oxygen consumed over a given period, the volume of blood that had been engaged in the carriage of this quantity can be calculated.

For example, by an actual measurement of oxygen in a femoral-artery blood a figure of 20 vol per cent may be obtained. This means that 20 cc of oxygen is present in each 100 cc of arterial blood. After the catheter is known to be in the right auricle by pressure measurement and fluoroscopic check, a blood sample taken from the auricle (mixed venous blood) might show a figure of 15 vol per cent — that is, 15 cc of oxygen per 100 cc of venous blood. In this hypothetical normal subject, the total oxygen used by all the tissues in a minute's time might measure 300 cc. Thus, it is seen that 5 cc of oxygen is taken up by the tissues per 100 cc of blood while at the same time the subject is consuming 300 cc of oxygen per minute, then 300 divided by 5 will give the units of blood in 100 cc flowing from the aorta (the oxygen content being practically the same as that of the femoral artery) to the right auricle, or the total systemic blood flow. In this case there would be 60 units of 100 cc, or 6 liters per minute. In the lungs the same principle holds, with the oxygen, of course, going into the blood, instead of coming out. If the catheter tip is placed in the pulmonary artery a blood sample may be obtained that might show a figure of 15 vol per cent, and that from the femoral artery (which is practically the same as the amount in the pulmonary vein) would again be 20 vol per cent. This would show that 5 cc of oxygen has been added to each 100 cc of blood flowing through the lungs. Then the pulmonary flow in such a case is

$$\frac{300}{20-15} \times 0.1 = 6 \text{ liters per minute}$$

The volume of flow through single, one-direction units may most easily be estimated by calculation

of the difference between the pulmonary and peripheral flows. If the shunt is in both directions more complicated formulas must be used.⁸⁵

By means of such measurements, the anatomic lesions in most cases can be predicted with a great deal of accuracy. Nevertheless, because of the inherent difficulties in making an exact diagnosis and the necessity for the therapeutic team to know as much about each patient's status as is humanly possible, radiographic studies should also be utilized.

Though the technic had previously been described, Robb and Steinberg⁵⁹ placed angiocardiology on a practical basis. The usual procedure is to inject 50 cc of double-strength diodrast as rapidly as possible in an antecubital vein. Multiple exposures are then taken, either manually or by use of special equipment, with the patient in an oblique position so that views will be obtained showing the bolus of opaque material in its passage through the various chambers of the heart, the lesser circuit, the great vessels and any abnormal communications that may be present (Fig 1).

As suggested by Getzoff⁹⁰ we have been having our subjects ingest several tablets of an antihistamine drug a short while before the dye is injected, to minimize allergic reactions. The procedure has been found to have almost no ill effect and has proved extremely valuable in differentiating obscure lesions.^{91, 92}

PATENT DUCTUS ARTERIOSUS

Patent ductus arteriosus, although originally noted by Galen,⁹³ has been known as the ductus Botalli since its alleged description by Botallus⁹⁴ (he was born in 1530). This curious by-play in medical history transpired when a charitable editor inserted an extra anatomic plate in a new system containing Botallus's observations, but long after his death.^{95, 96} Cristie⁹⁷ found that whereas 65 per cent of these vessels are still open at the end of two weeks of extrauterine life, only 1 per cent are patent after one year. It is estimated that there are approximately 20,000 people in this country with a patent ductus arteriosus. In Abbott's⁹⁸ review of 1000 cases, the incidence of patent ductus arteriosus was second only to that of intracardiac septal defects. In this malformation, as in a number of others, there is a curious sex distribution. For some unknown reason the defect is two or three times more common in females than in males.

Munro⁵³ demonstrated the feasibility of operation by performing ligations on newborn cadavers, but he stated that he tried in vain to inspire the pediatrician with his views. There still remains a difference of opinion regarding which cases should be selected for surgery. Taussig⁶² states that in general the prognosis varies with the size of the heart and that in the vast majority of cases the heart is but slightly enlarged. She claims that the out-

look is good, the malformation being compatible with a long and active life

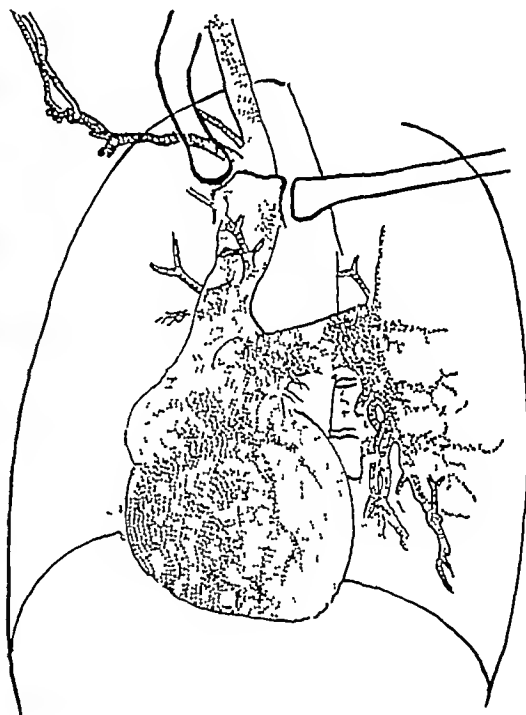

At variance are the statistical data of Abbott,⁹⁸ Bullock et al⁹⁹ and Keys and Shapiro¹⁰⁰ Abbott's mean age of death in 92 cases was twenty-four years (including, however, 20 patients who died in infancy) Bullock and his associates reviewed the cases of 80 patients, all over the age of three years proved by autopsy to have no other significant cardiac anomalies Half the patients died by the age of thirty, and 71 per cent were dead by the age of 40 years, 86 per cent died as a result of the con-

plications intervenes Very few survive once they develop failure (in marked contradistinction to patients with mitral disease)

Von Rokitsansky⁶⁷ showed in 1852 that the direction of flow was from the aorta to the pulmonary arteries This has been confirmed by Eppinger, Burwell and Gross¹⁰¹ who have also demonstrated that the volume of the leak in patients with large shunts constitutes up to 75 per cent of the blood expelled by the left ventricle, and because of this large volume of blood returned to the left ventricle without passing through the right, the output of the

A

B

FIGURE 1 Coarctation of the Aorta — Reproduction and Tracing of Unretouched Angiocardiogram Taken Eight Seconds after Injection of Dye into the Antecubital Vein
The right side of the heart and pulmonary arterial system are visualized

genital lesion — approximately half from bacterial endarteritis, and a fourth from congestive failure Excluding cases in infants and those with cyanosis, the probability that a patent ductus arteriosus will be associated with other significant anomalies is relatively small

Keys and Shapiro¹⁰⁰ analyzed 60 cases in adults (defined as persons over the age of seventeen) and found the life expectancy about half that of the population as a whole — roughly twenty-five years' reduction, or an average age at death of thirty-five years They claim that in the majority of cases the patient's life is fairly normal while it lasts Almost none are cardiac cripples As a rule, they maintain good compensation until one of the com-

left ventricle may be two to four times that of the right

Stunting of growth and underdevelopment are the results of the bypass of a large proportion of the oxygenated output of the left ventricle back into the pulmonary circuit There is a compensatory increase in the total volume of circulating blood both plasma volume and red-cell mass,¹⁰² but this is usually inadequate to meet nutritive requirements, although it must be remembered that many persons with a small shunt never have any disability as a result of the abnormality The diastolic pressure is usually low and upon exercise may drop to zero¹⁰³ The pulse pressure is usually wide, depending upon the volume of the shunt These findings

explain why with all but small shunts severe complications are prone to develop. Consequently, it is concluded that an attempt at ligation is justified in practically all cases, regardless of the absence of signs or symptoms of decreased adjustment to the defect.

The optimal time for operation is in childhood since adults are more likely to have less cardiac reserve, and frequently have an extremely short ductus arteriosus, which makes the operation more hazardous.¹⁰⁴ Gross¹⁰⁴ first did a ligation in continuity, and he stated that in children, when the ductus is soft, yielding, elastic and easily compressible, a ligation can almost always be relied upon to produce a permanent closure. In older patients, particularly in those beyond eighteen years of age, the vessel is frequently difficult to compress, and has an exaggerated pulsation transmitted to it by a sclerotic and fixed aorta. In these cases division and ligation, as first reported by Touroff,¹⁰⁵ have given best results.¹⁰⁶ Blalock,¹⁰⁷ who believes that routine division of the ductus arteriosus is an unnecessarily dangerous procedure, employs a method consisting of purse-string sutures at either end of the vessel, a through-and-through mattress suture between and a ligature of umbilical tape over the mattress suture.

Before the duct is tied, it should be compressed manually to be certain there is not an associated hypoplasia or stenosis of either great artery, in which case the ductus arteriosus functions as a necessary physiologic shunt.

Crafoord¹⁰⁸ reports that about half his 71 cases were ligated in continuity and about half divided. He has had only one recurrence (in a case in which the vessel was divided) and now covers the cut ends with a pericardial flap. There have been 2 deaths in his series.

Jones¹⁰⁹ prefers ligation in continuity and has operated in 61 cases with 2 deaths. He has also abandoned the anterior approach, used by most surgeons, and now employs a posterolateral one. An analysis of complications in his series revealed recurrence of murmur (10 cases), atelectasis (5 cases), empyema (2 cases), hemoptysis (2 cases) and paralysis of the recurrent laryngeal nerve (2 cases). Gross's¹⁰⁶ series numbered 180 cases at latest report, the ages varying from two to forty-six years, with 4 deaths. The average mortality in a series of 441 collected cases was 4.5 per cent.¹⁰⁶⁻¹¹³

COARCTATION OF THE AORTA

Coarctation of the aorta was described by Morgagni¹² in 1760. Subsequently Bonnet¹¹⁴ divided this anomaly into two groups: infantile and adult. The former is found in infants, most of whom die during the first year of life—the atresia generally involving the entire fetal isthmus of the aorta (the region from the left subclavian artery to the junction of the ductus arteriosus) and usually associated

with other major cardiac anomalies. Fortunately, this type is relatively uncommon (less than 5 per cent) although a narrow descending arch is a normal occurrence in fetal development.

The adult type is a more focal area of constriction, usually 1 cm or less in length, located most frequently at or just below the insertion of the ductus arteriosus. This type has been described in infants¹¹⁵ and the infantile type in adults,¹¹⁶ but since the adult form has no embryologic counterpart in normal intrauterine life, it is quite likely that the two types are fundamentally different anomalies.

Abbott¹¹⁷ searched all the available literature from the time of the earliest case report (1791) by Paris¹¹⁸ to 1928, collecting 200 cases. Reifstein, Levine and Gross¹¹⁹ had collected 104 additional cases up to 1947. They found that this defect is only occasionally compatible with long life, at least 61 per cent of patients dying before the age of forty (in Abbott's series the figure was 74 per cent). The average age at death was thirty-five years (thirty-three and a half years in Abbott's series). Again, there is a curious sex predilection, the lesion being more common in males, 5:1 (in Abbott's series, 4:1). Improvement in ante-mortem diagnosis had occurred since Abbott's report—40 per cent as compared with 14 per cent.

There is no evident relation between the degree of coarctation and the age at death or cause of death, which may be due to heart failure (18 to 29 per cent of cases), rupture of the aorta (20 to 23 per cent), bacterial endarteritis (16 to 22 per cent) or cerebral hemorrhage (10 to 12 per cent). Approximately a fourth of these patients die of incidental causes.

There does seem to be a direct relation between the degree of stenosis and the extent of collateral circulation, which produces the signs and symptoms of the disease and eventually the diagnosis. The majority of cases possess a grave degree of stenosis. A fourth of Abbott's patients were completely atretic, and in over 50 per cent of the remainder, the lumen was less than 6 mm in diameter.

The cardinal diagnostic features¹²⁰⁻¹²¹ include hypertension in the vessels of the upper extremity (frequently not marked), decreased pulse volume and blood pressure in the lower extremities, often associated with numbness and coldness, and collateral arterial anastomoses. These develop principally by way of the shoulder girdle (subscapular branch of the axillary artery, transverse scapular and cervical branches of the subclavian artery) and the anterior chest wall (internal mammary artery). As a result there may be pulsations or murmurs in unusual places, frequently interscapular or anteriorly adjacent to the sternum, or rib erosion¹²²—this important finding generally takes several years to appear so that x-ray evidence of it is frequently lacking in children (Fig. 2).¹²³

It should be emphasized that in the early decades of life, symptoms are usually absent, and a prompt

look is good, the malformation being compatible with a long and active life

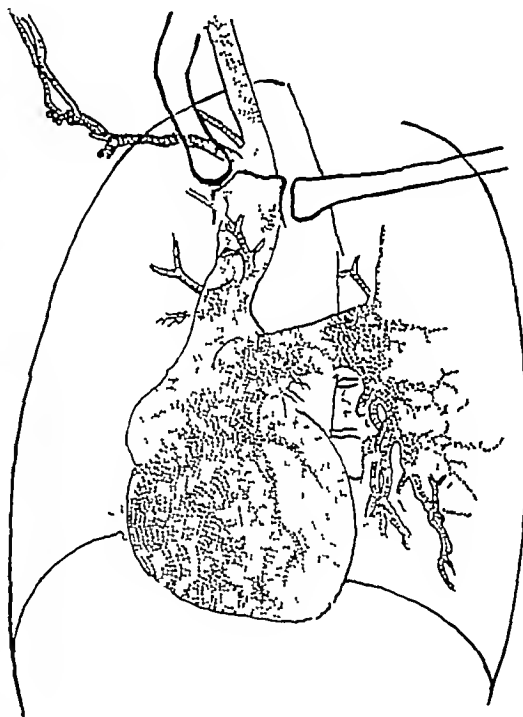

At variance are the statistical data of Abbott,⁹⁸ Bullock et al⁹⁹ and Keys and Shapiro¹⁰⁰ Abbott's mean age of death in 92 cases was twenty-four years (including, however, 20 patients who died in infancy) Bullock and his associates reviewed the cases of 80 patients, all over the age of three years proved by autopsy to have no other significant cardiac anomalies Half the patients died by the age of thirty, and 71 per cent were dead by the age of 40 years, 86 per cent died as a result of the con-

dition intervenes Very few survive once they develop failure (in marked contradistinction to patients with mitral disease)

Von Rokitsky⁶⁷ showed in 1852 that the direction of flow was from the aorta to the pulmonary arteries This has been confirmed by Eppinger, Burwell and Gross¹⁰¹ who have also demonstrated that the volume of the leak in patients with large shunts constitutes up to 75 per cent of the blood expelled by the left ventricle, and because of this large volume of blood returned to the left ventricle without passing through the right, the output of the

genital lesion — approximately half from bacterial endarteritis, and a fourth from congestive failure Excluding cases in infants and those with cyanosis, the probability that a patent ductus arteriosus will be associated with other significant anomalies is relatively small

Keys and Shapiro¹⁰⁰ analyzed 60 cases in adults (defined as persons over the age of seventeen) and found the life expectancy about half that of the population as a whole — roughly twenty-five years' reduction, or an average age at death of thirty-five years They claim that in the majority of cases the patient's life is fairly normal while it lasts Almost none are cardiac cripples As a rule, they maintain good compensation until one of the com-

plaints intervenes

Very few survive once they develop failure (in marked contradistinction to patients with mitral disease)

Stunting of growth and underdevelopment are the results of the bypass of a large proportion of the oxygenated output of the left ventricle back into the pulmonary circuit There is a compensatory increase in the total volume of circulating blood both plasma volume and red-cell mass,¹⁰² but this is usually inadequate to meet nutritive requirements, although it must be remembered that many persons with a small shunt never have any disability as a result of the abnormality The diastolic pressure is usually low and upon exercise may drop to zero¹⁰³ The pulse pressure is usually wide, depending upon the volume of the shunt These findings

explain why with all but small shunts severe complications are prone to develop. Consequently, it is concluded that an attempt at ligation is justified in practically all cases, regardless of the absence of signs or symptoms of decreased adjustment to the defect.

The optimal time for operation is in childhood since adults are more likely to have less cardiac reserve, and frequently have an extremely short ductus arteriosus, which makes the operation more hazardous.¹⁰⁴ Gross¹⁰⁴ first did a ligation in continuity, and he stated that in children, when the ductus is soft, yielding, elastic and easily compressible, a ligation can almost always be relied upon to produce a permanent closure. In older patients, particularly in those beyond eighteen years of age, the vessel is frequently difficult to compress, and has an exaggerated pulsation transmitted to it by a sclerotic and fixed aorta. In these cases division and ligation, as first reported by Touroff,¹⁰⁶ have given best results.¹⁰⁶ Blalock,¹⁰⁷ who believes that routine division of the ductus arteriosus is an unnecessarily dangerous procedure, employs a method consisting of purse-string sutures at either end of the vessel, a through-and-through mattress suture between and a ligature of umbilical tape over the mattress suture.

Before the duct is tied, it should be compressed manually to be certain there is not an associated hypoplasia or stenosis of either great artery, in which case the ductus arteriosus functions as a necessary physiologic shunt.

Crafoord¹⁰⁸ reports that about half his 71 cases were ligated in continuity and about half divided. He has had only one recurrence (in a case in which the vessel was divided) and now covers the cut ends with a pericardial flap. There have been 2 deaths in his series.

Jones¹⁰⁹ prefers ligation in continuity and has operated in 61 cases with 2 deaths. He has also abandoned the anterior approach, used by most surgeons, and now employs a posterolateral one. An analysis of complications in his series revealed recurrence of murmur (10 cases), atelectasis (5 cases), empyema (2 cases), hemoptysis (2 cases) and paralysis of the recurrent laryngeal nerve (2 cases). Gross's¹⁰⁶ series numbered 180 cases at latest report, the ages varying from two to forty-six years, with 4 deaths. The average mortality in a series of 441 collected cases was 4.5 per cent.¹⁰⁶⁻¹¹³

Gross's¹¹⁵ series numbered 180 cases at latest report, the ages varying from two to forty-six years, with $\frac{1}{2}$ deaths. The average mortality in a series of 441 collected cases was $\frac{1}{5}$ per cent.¹⁰⁷⁻¹¹²

COARCTATION OF THE AORTA

Coarctation of the aorta was described by Morgagni¹²¹ in 1769. Subsequently Bonnet¹²² divided this anomaly into two groups: infantile and adult. The former is found in infants, most of whom die during the first year of life—the atresia generally involving the entire fetal isthmus of the aorta (the region from the left subclavian artery to the junction of the ductus arteriosus) and usually associated

with other major cardiac anomalies. Fortunately, this type is relatively uncommon (less than 5 per cent) although a narrow descending arch is a normal occurrence in fetal development.

The adult type is a more focal area of constriction usually 1 cm or less in length located most frequently at or just below the insertion of the ductus arteriosus. This type has been described in infants¹²³ and the infantile type in adults¹²⁴ but since the adult form has no embryologic counterpart in normal intrauterine life it is quite likely that the two types are fundamentally different anomalies.

Abbott¹²⁵ searched all the available literature from the time of the earliest case report (1791) by Paris¹²⁶ to 1928 collecting 200 cases. Reifensstein, Levine and Gross¹²⁷ had collected 104 additional cases up to 1947. They found that this defect is only occasionally compatible with long life, at least 61 per cent of patients dying before the age of forty (in Abbott's series the figure was 74 per cent). The average age at death was thirty-five years (thirty-three and a half years in Abbott's series). Again, there is a curious sex predilection, the lesion being more common in males 51 (in Abbott's series, $\frac{4}{5}$). Improvement in ante-mortem diagnosis had occurred since Abbott's report—40 per cent as compared with 14 per cent.

There is no evident relation between the degree of coarctation and the age at death or cause of death, which may be due to heart failure (18 to 29 per cent of cases), rupture of the aorta (20 to 23 per cent), bacterial endarteritis (16 to 22 per cent) or cerebral hemorrhage (10 to 12 per cent). Approximately a fourth of these patients die of incidental causes.

There does seem to be a direct relation between the degree of stenosis and the extent of collateral circulation, which produces the signs and symptoms of the disease and eventually the diagnosis. The majority of cases possess a grave degree of stenosis. A fourth of Abbott's patients were completely atretic and in over 50 per cent of the remainder, the lumen was less than 6 mm in diameter.

The cardinal diagnostic features^{128, 129} include hypertension in the vessels of the upper extremity (frequently not marked), decreased pulse volume and blood pressure in the lower extremities, often associated with numbness and coldness, and collateral arterial anastomoses. These develop principally by way of the shoulder girdle (subscapular branch of the axillary artery, transverse scapular and cervical branches of the subclavian artery) and the anterior chest wall (internal mammary artery). As a result there may be pulsations or murmurs in unusual places, frequently interscapular or anteriorly adjacent to the sternum, or rib erosion¹³⁰—this important finding generally takes several years to appear so that x-ray evidence of it is frequently lacking in children (Fig. 2).¹³¹

It should be emphasized that in the early decades of life, symptoms are usually absent, and a prompt

explain why with all but small shunts severe complications are prone to develop. Consequently, it is concluded that an attempt at ligation is justified in practically all cases, regardless of the absence of signs or symptoms of decreased adjustment to the defect.

The optimal time for operation is in childhood since adults are more likely to have less cardiac reserve, and frequently have an extremely short ductus arteriosus, which makes the operation more hazardous.¹⁰¹ Gross¹⁰¹ first did a ligation in continuity, and he stated that in children, when the ductus is soft, yielding, elastic and easily compressible, a ligation can almost always be relied upon to produce a permanent closure. In older patients, particularly in those beyond eighteen years of age, the vessel is frequently difficult to compress, and has an exaggerated pulsation transmitted to it by a sclerotic and fixed aorta. In these cases division and ligation, as first reported by Touroff,¹⁰⁵ have given best results.¹⁰⁶ Blalock,¹⁰⁷ who believes that routine division of the ductus arteriosus is an unnecessarily dangerous procedure, employs a method consisting of purse-string sutures at either end of the vessel, a through-and-through mattress suture between and a ligature of umbilical tape over the mattress suture.

Before the duct is tied, it should be compressed manually to be certain there is not an associated hypoplasia or stenosis of either great artery, in which case the ductus arteriosus functions as a necessary physiologic shunt.

Crafoord¹⁰³ reports that about half his 71 cases were ligated in continuity and about half divided. He has had only one recurrence (in a case in which the vessel was divided) and now covers the cut ends with a pericardial flap. There have been 2 deaths in his series.

Gross's¹⁰⁶ series numbered 180 cases at latest report, the ages varying from two to forty-six years, with 4 deaths. The average mortality in a series of 441 collected cases was 4.5 per cent.¹⁰⁶⁻¹¹³

COARCTATION OF THE AORTA

Coarctation of the aorta was described by Morgagni¹³ in 1760. Subsequently Bonnet¹¹⁴ divided this anomaly into two groups: infantile and adult. The former is found in infants, most of whom die during the first year of life — the atresia generally involving the entire fetal isthmus of the aorta (the region from the left subclavian artery to the junction of the ductus arteriosus) and usually associated

with other major cardiac anomalies. Fortunately, this type is relatively uncommon (less than 5 per cent) although a narrow descending arch is a normal occurrence in fetal development.

The adult type is a more focal area of constriction, usually 1 cm or less in length, located most frequently at or just below the insertion of the ductus arteriosus. This type has been described in infants¹¹⁵ and the infantile type in adults,¹¹⁶ but since the adult form has no embryologic counterpart in normal intrauterine life, it is quite likely that the two types are fundamentally different anomalies.

Abbott¹¹⁷ searched all the available literature from the time of the earliest case report (1791) by Paris¹¹⁸ to 1928, collecting 200 cases. Reifenshein, Levine and Gross¹¹⁹ had collected 104 additional cases up to 1947. They found that this defect is only occasionally compatible with long life, at least 61 per cent of patients dying before the age of forty (in Abbott's series the figure was 74 per cent). The average age at death was thirty-five years (thirty-three and a half years in Abbott's series). Again, there is a curious sex predilection, the lesion being more common in males, 5:1 (in Abbott's series, 4:1). Improvement in ante-mortem diagnosis had occurred since Abbott's report — 40 per cent as compared with 14 per cent.

There is no evident relation between the degree of coarctation and the age at death or cause of death, which may be due to heart failure (18 to 29 per cent of cases), rupture of the aorta (20 to 23 per cent), bacterial endarteritis (16 to 22 per cent) or cerebral hemorrhage (10 to 12 per cent). Approximately a fourth of these patients die of incidental causes.

There does seem to be a direct relation between the degree of stenosis and the extent of collateral circulation, which produces the signs and symptoms of the disease and eventually the diagnosis. The majority of cases possess a grave degree of stenosis. A fourth of Abbott's patients were completely atretic, and in over 50 per cent of the remainder, the lumen was less than 6 mm in diameter.

The cardinal diagnostic features¹²⁰⁻¹²¹ include hypertension in the vessels of the upper extremity (frequently not marked), decreased pulse volume and blood pressure in the lower extremities, often associated with numbness and coldness, and collateral arterial anastomoses. These develop principally by way of the shoulder girdle (subscapular branch of the axillary artery, transverse scapular and cervical branches of the subclavian artery) and the anterior chest wall (internal mammary artery). As a result there may be pulsations or murmurs in unusual places, frequently interscapular or anteriorly adjacent to the sternum, or rib erosion¹²² — this important finding generally takes several years to appear so that x-ray evidence of it is frequently lacking in children (Fig 2).¹²³

It should be emphasized that in the early decades of life, symptoms are usually absent, and a prompt

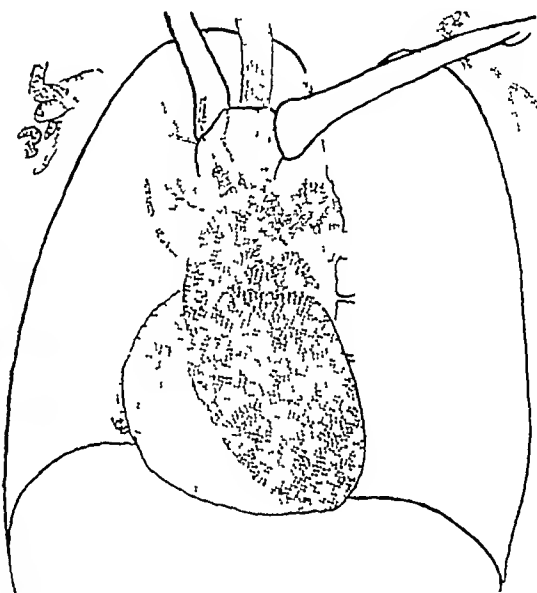

diagnosis will not be made unless there is a careful study of all young patients. Even then the clinical picture may be obscure, and in these cases contrast visualization of the great vessels is an important adjunct in the study of the patient.¹²⁴

The first suggestion of definitive therapy was made by Blalock and Park.¹²⁵ They investigated the feasibility of anastomosing the subclavian artery to the aorta, distal to the constriction, and performed the operation on dogs, suggesting that the left common carotid artery might be a better vessel to use in human beings. Crafoord,¹²⁶ of Stock-

the lateral one, forming a T. The vascularity of the region is tremendously increased, so that blood loss may be great. The aorta is dissected free and the ligamentum arteriosum cut, care being taken to avoid the left vagus and recurrent laryngeal nerve as well as the thoracic duct. After resection of the coarctation, the aorta is anastomosed with either one or two rows of sutures. Either interrupted sutures or a continuous U-suture may be used, the ends being everted so that intima is in contact with intima. The proximal clamp on the aorta must be released gradually over a period of five to six

A

B

FIGURE 2 Same Patient as That in Figure 1

The time is five and a half seconds later. The dye has returned from the lungs and is visible in the left side of the heart, ascending aorta and great vessels of the neck. Note visualization of the coarctation of the aorta and dilated and tortuous subscapular vessels.

holm, reasoned that since the human subject had developed a tolerance to poor aortic blood flow distal to the stenosis, the aorta in these patients could be safely occluded for as long a period as was necessary to excise the stenotic area and do an end-to-end anastomosis. He performed the first two operations, both on male patients, in October, 1944—one twelve years old and the other twenty-seven years old. Both survived.

Gross¹²⁷ independently had arrived at similar conclusions, and he was next to perform the operation in June, 1945. He uses cyclopropane anesthesia and has adopted a posterior thoracic approach through the bed of the fourth rib. Segments of the posterior ends of the third, fifth and sixth ribs are also removed in a vertical incision that connected

minutes to prevent circulatory failure,¹²⁸ since venous return to the heart may be temporarily diminished during the time that the depleted vascular system of the lower portion of the body adjusts itself to its increased blood volume. (Crafoord¹²⁶ states that he has had no difficulty with rapid release of this clamp.)

Clagett¹²⁹ has had to use the procedure originally suggested by Blalock because of technical difficulties, and in a discussion at a recent meeting it was stated that he has employed this procedure on five occasions with 1 death, the ages varied from eighteen to thirty-four years.¹³⁰ In each case severe degrees of aortic sclerosis were noted—a finding important to the thesis that all patients with coarcta-

tion should be operated upon early to obviate degenerative sequelae

Operative intervention is the only definitive treatment, although the not infrequent concomitant finding of congenital intracranial aneurysm (5 to 10 per cent of cases) and bicuspid aortic valves (25 to 40 per cent) militate somewhat against the hopeful results to be expected from surgery. The optimal time for operation is in the second decade.

Below the age of six or seven the aorta is generally too small to work on satisfactorily, and over the age of twenty-five to thirty, it is apt to be sclerotic above the obstruction or thinned out below. Gross¹²¹ reports 40 explorations, of which 35 were resectable. There were 5 deaths. There has been a diminution of hypertension in the upper extremities to normal

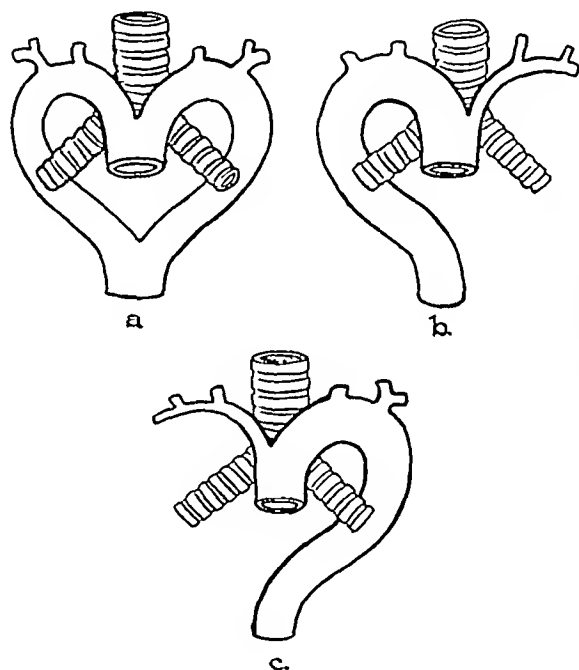

FIGURE 3 Comparative Anatomy of the Aortic Arch

A=retention of primitive double aortic arch—found in frogs, cause of so-called “aortic ring” in human beings. B=retention of right aortic arch, a normal occurrence in birds (seen in approximately 20 per cent of cases of tetralogy of Fallot). C=arching of aorta to the left, the usual occurrence in the human being (many variations of these three basic types of development may be encountered).

in all but one case associated with increase in pulsation and rise in arterial pressure of the leg vessels

PULMONARY STENOSIS AND ATRESIA

Stenosis or atresia of the pulmonary artery was present in 150 of 1000 cases reported by Abbott⁹⁸. About 25 per cent were not associated in the manner described below. The remainder were generally classified as cases of tetralogy of Fallot—that is, pulmonary stenosis or atresia, defect of the inter-

ventricular septum, dextroposition of the aorta (discussed below) and hypertrophy of the right ventricle. This is the most frequently encountered type of congenital cardiovascular defect associated with cyanosis.

Operative experience has led Blalock¹²² to emphasize the fact that in approximately 20 per cent

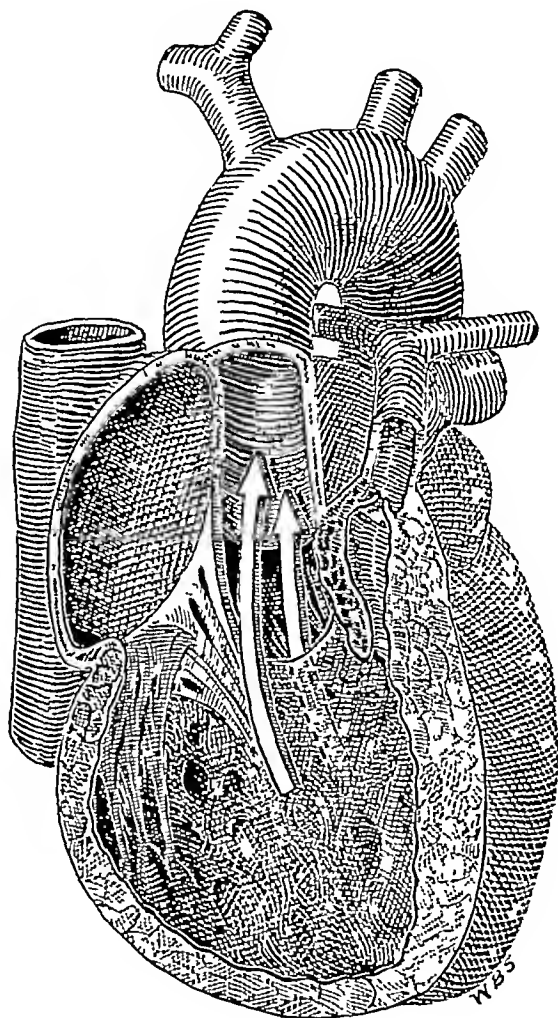

FIGURE 4 Diagrammatic Representation of the Heart in Tetralogy of Fallot, with the Outer Wall of the Right Ventricle Removed

Note the stenosis of the pulmonary artery, interventricular communication, deviation of the aortic orifice to the right and hypertrophy of right ventricle

of operative cases the aorta will be seen arching to the right instead of its usual course to the left, and descending on the right side rather than the left (Fig 3). Thus the aortic arch and descending aorta are dextroposed. This has given rise to an ambiguity in terminology, and, as suggested by Rives,¹²³ it is urged that the orifice of the aorta be referred to as dextroposed when the tetralogy of Fallot is described. As a matter of fact, the fault

lies not with Fallot,¹³⁴ but with his translators, for he was perfectly clear in describing "stenosis of the pulmonary artery, interventricular communication, deviation of the origin of the aorta to the right, and hypertrophy, almost always concentric, of the right ventricle" (Fig 4). Thus, all cases of *la maladie bleue* are associated with a dextroposition of the aortic orifice, only 20 per cent of these patients have a right aortic arch and descending aorta. (This

per 100 cc, and the red-cell count may become as high as 12,000,000.¹³⁷

It was formerly assumed that all the blood that passed through the lungs was not fully oxygenated, so that most investigators believed that a further increase in the circulation of the blood to the lungs would be of no benefit. However, it was observed that the condition of children with pulmonary stenosis and associated patent ductus arteriosus

A

B

FIGURE 5 Unretouched Angiocardiogram in Tetralogy of Fallot

A. Five seconds after injection of the dye, which is concentrated in the superior vena cava and right side of the heart. B. Two and a half seconds later (or the same time as that in Figure 1) instead of entering the pulmonary circulation, most of the flow is shunted through the displaced aortic orifice into the systemic circulation, a small amount is entering the stenotic pulmonary artery.

is the usual occurrence in birds,¹³⁵ and might be referred to as the "bird aorta.")

Although simple defect of the ventricular septum (*maladie de Roger*) is a relatively common congenital anomaly and can be well tolerated, its association with hypoplasia of the pulmonary artery results in a serious clinical syndrome. Instead of the blood flowing through the defect from the left ventricle to the right ventricle, the stenosis obstructs the pulmonary circulation sufficiently to reverse the direction of the flow in the ventricles. Aeration of the resultant small amount of circulating blood in the pulmonary circuit is not sufficient to prevent cyanosis, which occurs in the presence of 5 gm of reduced hemoglobin per 100 cc of blood.¹³⁶ The value for the total hemoglobin may become 26 gm

became worse if the duct was closed, thereby reducing further the flow of blood to the lungs. Consequently, Taussig⁶² proposed that these patients might be improved if a means could be devised whereby a greater volume of blood could reach the lungs.

On the basis of this suggestion, Blalock¹³² devised an operation in which a systemic artery was anastomosed to one of the pulmonary arteries and thus increased the pulmonary flow. Doyen⁶⁴ was the pioneer in this particular location, having attempted in 1913 to divide what was believed to be a stenotic valve with a tenotome knife. The patient died several hours later, and examination revealed the usual finding — namely, that the defect is commonly in the pulmonary conus rather than in the

valve itself (Recent work of Brock is discussed below)

In untreated cases of pulmonary stenosis the life expectancy is only twelve and a half years, with a maximum of about twenty-five years. Chief complications are cardiac failure, poor development, pulmonary tuberculosis, cerebral thrombosis and bacterial endarteritis.

The underlying principle in the choice of patients for operation is that there must be an inadequate flow of blood to the lungs. The two outstanding diagnostic features are roentgenographic evidence that the pulmonary artery is small and clinical and roentgenographic evidence of absence of congestion in the lung fields.

Additional information concerning the pathologic physiology of congenital heart disease has been supplied by Bing et al.¹³³ and by Dexter and his group.⁵³ In employing the method of intravenous catheterization for studying cardiac dynamics, Bing, Vandam and Grav¹³³ have been able to measure the outputs and pressures of the various chambers of the heart, the pulmonary artery and the total pulmonary flow, including that through the collateral channels. This has enabled them to make exact differential diagnoses in difficult cases. Bing states that the three most important indications for surgical creation of an artificial ductus arteriosus are a decrease in effective pulmonary blood flow, a reduction in pulmonary-artery pressure, and a diagnosis of intracardiac shunt. The limitations and potentialities of such methods have been described by Dexter et al.⁵³ Auricular and ventricular septal defects offer greater difficulty in diagnosis. Also of distinct value is visualization of the chambers of the heart and great vessels¹³⁹ (Fig 5) — a procedure just being adopted for routine use in many centers.¹⁴⁰

The preferred age for operation is from five to nine years, since the infant mortality is approximately 30 per cent as compared to one of 10 per cent for children.¹⁴¹ Taussig¹⁴² does not advise operation in those eighteen months and younger, unless the infant is doing very poorly and it appears that the chances of survival to an old age are less than 50 per cent. The early development of attacks of paroxysmal dyspnea is an unfavorable sign. The period of greatest difficulty occurs when the ductus arteriosus is being obliterated — usually between six and eighteen months. As collateral circulation and compensatory polycythemia develop (one to three years) attacks of dyspnea diminish. Most infants who survive until eighteen months of age manage to hold their own for a time, and then begin to improve.

Leeds¹⁴³ showed in dogs that anastomosis of the aorta to the pulmonary artery could be done. Utilizing this approach and by means of an ingenious clamp, which, although reducing the aortic lumen, still allows approximately 50 per cent

flow during its application, Potts et al.^{144, 145} are doing aortic-pulmonary anastomoses. Advantages are that the shunt can be made whatever size is deemed necessary, and that the innominate artery can be conserved in younger patients. At last report they have operated on 41 patients for pulmonary stenosis, 10 below the age of two and three below one year of age. Potts reports 4 deaths in this series.

The anastomosis of the left subclavian artery to the left pulmonary artery is advocated by Holman.¹⁴⁶ Because of sharp angulation of the subclavian artery in 4 cases, he has deliberately divided the left pulmonary artery proximal to the anastomosis, and has noted no subsequent detrimental effects.

Blalock¹⁴⁷ still prefers an end-to-side anastomosis, using the subclavian artery in most patients who are more than two years of age. The desired aim is to choose a systemic artery of such caliber that the polycythemia and cyanosis will disappear but not large enough to place undue strain on the heart. The incision in the chest is usually made on the side opposite to that which the aorta descends (as mentioned above). It is desirable to use the subclavian branch of the innominate rather than the opposite subclavian, which arises directly from the aorta, since the former makes a less acute angle with its parent artery after the anastomosis is performed.

Preoperative studies will have given a good indication of the size of the artery required — the greater the degree of arterial oxygen unsaturation, the larger the vessel that is needed. It has been found that the pressure in the pulmonary artery as determined at the time of operation is generally equivalent to 150 to 240 mm of water. If the pressure is elevated in excess of 300 mm approaching or equaling the aortic pressure, the chances are that there is an absence of the ventricular septum, and the procedure should be canceled since the flow of blood inevitably depends upon the relative pressure between the systemic and pulmonary circulations.¹⁴⁷

If the patient has pronounced polycythemia and if the loss of blood during the operation is minimal, whole blood equal to approximately 1 per cent of the body weight is removed at the conclusion of the operation. It has been found that there need be no concern about the circulation of the arm when the subclavian artery is used, however, when the innominate artery is divided there is danger of cerebral ischemia or thrombosis.

Up to the present time Blalock and his associates have operated upon 415 patients, who were thought to have tetralogy of Fallot. The over-all mortality, including deaths among those in whom an anastomosis could not be performed, those in whom the diagnosis was in error and those who have died since leaving the hospital, has been reduced to 18 per cent. In 283 cases in which the subclavian

artery was used for the shunt the mortality was 10 per cent. On the other hand, when the carotid or innominate artery was utilized,¹³² the rate was approximately 30 per cent. It should be emphasized that surgery is not indicated for cor biloculare or cor triloculare, persistent truncus arteriosus and Eisenmenger's complex — distinguished from the tetralogy of Fallot by a normal or even dilated pulmonary artery.

RECENT DEVELOPMENTS

Some of the remaining anomalies are being ameliorated or remedied by surgical procedures. Others are in the process of investigation in the experimental laboratory.

Gross,¹⁴⁸ in 1945, reported the first successful surgical division of a congenital vascular ring around the trachea.

Tricuspid atresia, until recently considered inoperable,¹⁴⁹ has now come to surgery. Potts and Gibson¹⁵⁰ described 3 patients successfully operated upon with performance of aortic-pulmonary anastomosis. The physical findings in this anomaly are identical with those encountered in the tetralogy of Fallot. Differential features are left-axis deviation in the electrocardiogram (the only lesion that causes cyanosis and has this characteristic) and hypertrophy of the left ventricle and hypoplasia of the right ventricle, which produces a suggestive roentgenographic silhouette.

Shumacker¹⁵¹ has recorded the first case of coarctation of the aorta complicated by a saccular aneurysm just distal to the stenosis successfully treated (February, 1947) by resection of the stenotic area and aneurysm with repair of the aorta by end-to-end anastomosis. Alexander and Byron¹⁵² had a similar case, which was successfully treated by resection alone without anastomosis.

Brock¹⁵³ has recently recorded his experiences with the direct approach of Doyen to the pulmonary valve in cases of pulmonary stenosis. This method was restudied because of his belief that the stenosis is purely valvular or diaphragmatic in a proportion of cases far higher than heretofore supposed. He examined the valves, at operation, by means of a cardioscope inserted through the pulmonary artery, but has decided that this approach is unsatisfactory.

The first patient was operated on in February, 1948. A valvulotome was inserted through an incision in the wall of the right ventricle and used to divide the pulmonary valves. A special dilating forceps was then passed and opened fully in the region of the stenosis. The patient, an eighteen-year-old girl, survived and showed decided improvement subsequently. The procedure has been repeated in 2 more cases, in both of which the patients survived. This operation is not meant to supplant the Blalock procedure, but it does have definite advantages in cases in which the stenosis involves the pulmonary valve itself rather than the pulmo-

nary conus. The exact proportion of such cases will have to be reinvestigated, but this work of Brock's represents another pace-setting advance. (In 155 cases of pulmonary tract anomalies studied by Keith,¹⁵⁴ a defect was found in the pulmonary conus in 133, and in the pulmonary valve alone in 22, he estimated that the pulmonary conus would be involved in 90 per cent of the cases.)

Hanlon and Blalock¹⁵⁵ have recently shown experimentally that anastomosis of the pulmonary vein to the superior vena cava can be done. If feasible in man, this delicate procedure offers a possible approach to the surgical treatment of complete transposition of the aorta and pulmonary artery.

Utilizing the same approach and occlusive clamp, but shifting the operative field slightly distalward, the same workers¹⁵⁶ have been able to obtain an entirely different result — that is, the production of an interatrial septal defect under direct vision, without interruption of the circulation, with minimal loss of blood and with fairly accurate control of size — truly a brilliant achievement. Though he suggested a blind approach through the jugular vein, Jarotzky¹⁵⁷ apparently was the first to recommend such a shunt, knowing that the patient with a mitral stenosis associated with an open foramen ovale (Lutembacher¹⁵⁸ syndrome) has a comparatively good prognosis (forty years¹⁵⁹).

Gibbon and Templeton¹⁶⁰ have recently reconstructed and replaced leaflets of the tricuspid valves with pericardial and venous grafts in dogs.

In the field of myocardial ischemia Beck¹⁶¹ has continued pre-eminent in the search for methods to revascularize the heart. Louis Gross^{162, 163} made the important discovery that ligation of the coronary sinus produced extensive and abundant dilatation of the intramyocardial collateral channels. Sutton and Lueth¹⁶⁴ found that the pain fibers involved in experimental coronary occlusion are located in the adventitia of the coronary artery. Fauteux¹⁶⁵ combined these last two facts by ligating the magna cordis vein alone (more distal than the coronary sinus) or combined with pericoronary stripping in a total of 15 patients over a six-year period. His results are encouraging.

In view of these advances J. T. Roberts¹⁶⁶ (another internist), suggested to Beck¹⁶¹ the possibility of making an arteriovenous fistula to the heart to increase a deficient blood supply. Utilizing various cannulae¹⁶⁶ as well as the Potts clamp, Beck and his workers have been successful in grafting a systemic artery into the coronary sinus in dogs. They have recently reported the first case (January, 1948) in a human being in which a new connection was made from the aorta to the heart with a transplanted segment of brachial artery. The patient recovered from this extraordinary operation.

Gross and his associates¹⁶⁷ report encouraging early postoperative results after the use of arterial

transplants in the treatment of cardiovascular defects

Polished tubes of a plastic (methyl methacrylate) material containing a movable valve were inserted in the aorta by Campbell¹⁶⁵ in dogs with surgically produced aortic valvular insufficiency. Clotting of blood about the moving valve did not occur for the length of time the animals were observed. The clinical use of such materials, particularly polythene, has a promising future in surgery.¹⁶⁹⁻¹⁷⁰

Smithy et al.¹⁷¹⁻¹⁷² are reinvestigating the use of the valvulotome as applied to aortic stenosis. The instrument was first introduced through the aorta, but later work has shown that the wall of the left ventricle offers the most effective approach. This approach was also found best by both Cushing²¹ and Bernheim²⁵ forty years ago. In those days MacCallum²³ and Allen³² were introducing their valvulotomes and cardioscopes through the left auricular appendage. Cushing reported the first successful attempt to produce valvular lesions of the heart by an intrathoracic approach. He emphasized then that a successful operation must be done on the animal before being attempted on man.

* * *

Some understanding of the surgical approach to cardiovascular disease has become mandatory for the present-day clinician. The recent advances in treatment of pulmonary stenosis, coarctation of the aorta, anomalies of the aortic arch and patent ductus arteriosus are brilliant and promising refinements in the art of surgery. In fact, their diagnosis and treatment are now on a highly scientific plane. The operative treatment of acquired cardiac disease has been reintroduced. Further technical advances are bound to occur. Such intricate and involved procedures call for highly trained and skilled groups of workers — cardiologists, pediatricians, surgeons, anesthetists, roentgenologists, physiologists and probably others. Whether such procedures can or should be done by the average well trained surgeon in the average hospital is doubtful. On the other hand, whether it is economically or socially wise for the patients requiring these procedures to go to special regional centers is also a moot question. Physicians and surgeons should lead the way not only in introducing these new methods but also in discussing and suggesting means to assure their availability to all groups in all regions of the country.

I am indebted to Dr Teitelbaum, of the Department of Radiology, Touro Infirmary, and to Dr Gouaux, of the Heart Station, Charity Hospital of Louisiana, for permission to reproduce the angiograms.

CASE 35011*

PRESENTATION OF CASE

A twenty-two-year-old woman was admitted to the hospital complaining of pain in the left leg

Ten years before admission, following a fall, she had pain in the lower back for several months. Six weeks before admission she began to notice pain along the anterior aspect of the proximal third of the left lower leg, deep within the muscle group. This leg pain was "wave-like, deep and boring." It was fairly constant and more marked after exercise, but not incapacitating. It did not keep her from sleeping, except to waken her early in the morning. The pain sometimes radiated up the posterior thigh and lower back but never farther distally than the mid-lower leg. In the week before admission she noticed weakness of the left foot when she was tired.

On physical examination the left calf was 0.6 cm larger than the right, and there was questionable prominence of the head of the left fibula. There was no calf tenderness or sensory change. The muscle power in the foot and ankle was equal bilaterally. There was slight tenderness in the left buttock. The ankle jerks were equal, the knee jerk seemed to be more active on the left.

The blood pressure was 140 systolic, 92 diastolic. Examination of the blood demonstrated a normal white-cell count, hemoglobin and urine. The sedimentation rate was 4 mm in one hour. The blood calcium was 9.8 mg, and the phosphorus 4.1 mg per 100 cc, and the alkaline phosphatase 2.8 units.

X-ray examination of the skull, lumbar spine and pelvis was not remarkable. There was no evidence of bone destruction or alteration of the intervertebral spaces. Examination of the left knee showed no joint abnormalities. There was a small radiolucent area 7 mm wide and 15 mm long in the medulla of the proximal third of the fibula. There were one or two small, irregular septums within the lesion, the margin of which was smooth and slightly sclerotic. The overlying cortex was

slightly elevated, but there was no break in the cortex and no periosteal reaction (Fig 1).

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM ELLIOT† I think we can rule out anything in the spine because of the absence of sensory changes in the leg, muscle weakness and the fact that there is no atrophy. As far as the skull is concerned, I see nothing there that is of interest, and I see nothing remarkable in the dorsal spine.

In consideration of a lesion in the bone we either consciously or subconsciously decide that it is infection or a tumor. In this case I believe we can more or less rule out an infectious process, certainly, it was not an acute infectious process. If it was a tumor, it forces us into a large group of possibilities, and first we must decide whether it was malignant or benign. There is nothing to indicate that this

FIGURE 1

was a malignant tumor. There was no new-bone formation, periosteal proliferation or any of the other stigmas we expect to see in malignant tumor.

As to the other conditions that this may represent, I think we can rule out hyperparathyroidism on the blood chemical findings as reported here. In most of the lesions of hyperparathyroidism that we have encountered there has not been an increase in thickness of the cortex over the lesion. Usually the cortex has been thinned out, and this is also the x-ray finding in fibrous dysplasia and certain

*Presented at a meeting of the New England Cancer Society held at the Massachusetts General Hospital.

†Radiologist Worcester Memorial Hospital Worcester Massachusetts.

other lesions. As I said before, this apparent thickening of the cortex at the site of the lesion is important. There is a condition described by Jaffe and Lichtenstein¹ as nonosteogenic fibroma, which is benign and, to my knowledge, gives no symptoms. It may occur along the shaft of the long bones, and in a case that we have followed over a period of years there was definite thinning of the cortex, but no symptoms referable to the site of the lesion. The nonosteogenic fibromas produce no symptoms and, as a rule, are incidental findings.

Another possibility is a cartilage inclusion, which occurred at the time the line of the epiphysis was at the site of the present lesion, and moved down the shaft with the increase in the length of the bone. Nothing is said about point tenderness—a finding usually present in osteoid osteoma. Whether or not osteoid osteoma is a clinical entity or the result of low-grade infection I will not discuss at this time. I believe this was an osteoid osteoma, and I base this opinion on the fact that these lesions may occur in the medullary cavity against the inner surface of the cortex or within the cortex itself. Pain is the symptom that causes these patients to seek medical advice. Pain, as a rule, is slow in onset, it becomes more aggravated as time goes on, and it may be quite constant. The physical findings are more or less absent except for point tenderness over the lesion itself. Or there may be slight swelling about the lesions, which this patient had. I do not believe this was eosinophilic granuloma because again there is usually bone destruction and a little more reaction about the lesion itself in that condition.

Regarding the operation that this patient had, I believe it was a simple excision of the lesion, with possible preservation of the cortex away from the lesion.

DR GRANTLEY W. TAYLOR: I wonder why Dr Elliot did not allude to benign giant-cell tumor in that area.

DR ELLIOT: I should have. Benign giant-cell tumor does occur along the shaft. A giant-cell tumor of the size of this lesion would have been asymptomatic, and again there is thinning of the cortex as a rule at the site of the tumor. This cortex was a little elevated and thickened, which I believe is against benign giant-cell tumor.

DR JAMES W. JAMESON: Do you place any significance on the pain occurring at night?

DR ELLIOT: That frequently happens in cases of osteoid osteoma.

DR PHILIP BATCHELDER: Does it have a nidus in the center?

DR ELLIOT: There is a small area of increased density in the cortex, but I cannot be sure that this represents the nidus. I believe Jaffe² states that the nidus may disappear as the lesion matures.

DR GEORGE C. LEVENE: I would agree that from the description this was osteoid osteoma.

DR DOUGLAS J. ROBERTS: Would you consider fibrous dysplasia?

DR ELLIOT: I had considered that. Quite frequently the cortex shows a little thickening and may be bulging, of course, but usually there is a little thinning and not the elevation that this patient had. I think you can see on the films a definite thickening of the cortex as it comes up along there, which

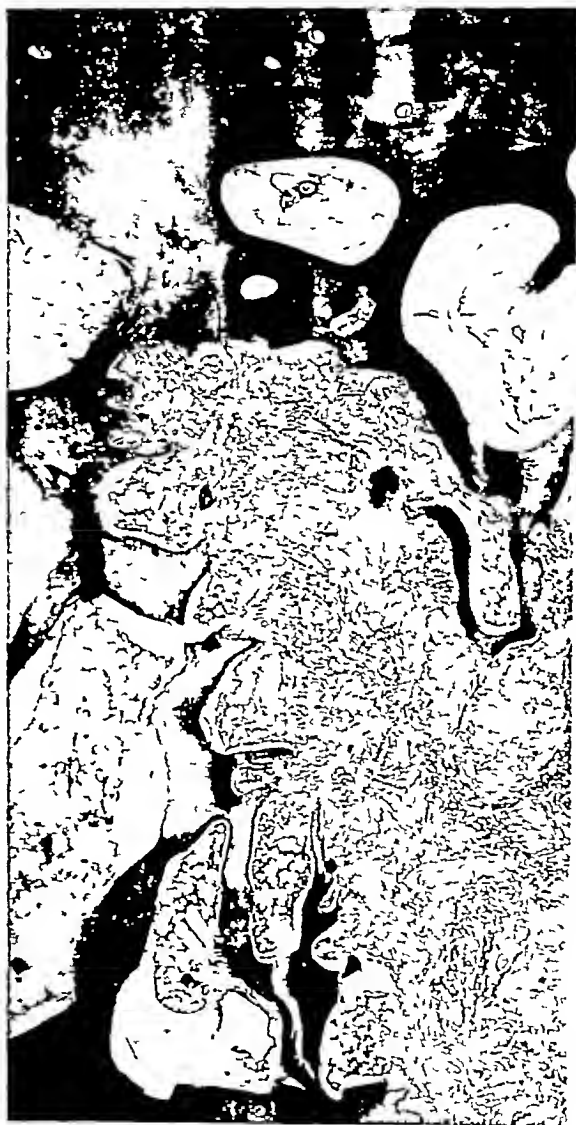

FIGURE 2

I believe is the sclerosis that has been described in the osteoid osteoma.

CLINICAL DIAGNOSIS

Benign tumor

DR ELLIOT'S DIAGNOSIS

Osteoid osteoma

ANATOMICAL DIAGNOSIS

Nonosteogenic fibroma of bone (fibula)

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN This patient was operated on by Dr Edwin Cave, who resected the lesion in toto. I have some microscopical sections of it, which I will show. The first slide (Fig 2) is a low-power view of the lesion showing cortical

FIGURE 3

bone at the top and a loose fibrous lesion in the medulla. Note the normal fatty marrow around part of the lesion. A higher magnification (Fig 3) shows that the lesion is made up almost entirely of thin, spindle-shaped fibroblasts without any evidence of osteogenesis. In addition, there are a great many cells filled with fat, which are undoubtedly

merely phagocytes. The whole picture fits in exactly with what Jaffe¹ called nonosteogenic fibroma. It is about the second or third case that we have seen here. These tumors, according to Jaffe, do produce occasional symptoms. I do not believe they are all symptomless. They often cause pain and almost always occur in children between the ages of eight and sixteen, usually under twenty in contrast to giant-cell tumor, which occurs almost always above twenty. It is a tumor that in the past has been called a variant of giant-cell tumor. It certainly does not look at all like osteoid osteoma. The lesion is perfectly benign.

DR ELLIOT I thought that the lesions were always incidental findings.

DR CASTLEMAN In his report of 10 cases Jaffe stated that in half there was a history of trauma that apparently attracted attention to the area where the lesion was found by x-ray examination.

DR CLINTON MULLINS How can you differentiate that from a healed osteomyelitis?

DR CASTLEMAN There is no evidence of inflammation at all, and the type of connective-tissue cell is very dense, without any cellular reaction.

CASE 35012

PRESENTATION OF CASE

A forty-eight-year-old carpenter was transferred from another hospital because of an abdominal-incision dehiscence and draining small-bowel fistula.

The patient had been well and working up until three months before entry, when he began to feel dull, "crampy" pains in the epigastrium, lasting a few minutes. These occurred several times a day and were relieved by two or three glasses of whisky. They were not related to meals. The patient stated that for many months he had often had a desire to defecate without success. Five weeks before admission the pains became more severe and frequent. He stopped work and started drinking as much as a pint of whisky each morning, with little relief of pain but with nausea and vomiting of gastric contents. One week later the pain suddenly became very severe after he had taken a large glass of whisky. He became "pale and dizzy," and his upper abdomen "very hard." He was very weak and drove his car home with great difficulty. His abdomen was painful to touch. The following day he was admitted to another hospital. Physical examination revealed an obese, middle-aged man complaining of upper abdominal pain. His face was flushed and he perspired profusely. His temperature and pulse were normal. The chest was

clear and resonant throughout. The upper part of the abdomen was distended, firm and very tender. The lower part of the abdomen was much softer and not distended. The abdomen was tympanic, and peristaltic movements could not be heard. Repeated enemas gave no results. In the other hospital the patient's temperature remained at 99°F, and the pulse was normal for three days. The distention became greater, and the pain generalized. There was difficulty in breathing. He at no time vomited or felt like vomiting. A Wangensteen tube was introduced, and a large amount of fluid recovered in a twenty-four-hour period. The following day his condition was worse. A diagnosis of retrocecal appendix was made, and a laparotomy done. The large bowel was distended. The intestine showed acute enteritis bordering on a purple color. The appendix was perfectly normal and was removed. A colostomy was performed to relieve the distention. The distention persisted. Three days later a fecal fistula formed about 8 cm above the colostomy opening. There was induration below the colostomy, with questionable abscess formation. Two days later the abscess was drained, and the patient improved. His appetite was better. After a period of two weeks there seemed to be a breaking down of the incision, owing to the fecal fistula and colostomy. The patient was given penicillin and intravenous fluids. Following this he developed dyspnea and marked perspiration. Intravenous fluids were cut down to 500 cc three times a day. He had been taking moderate amounts of fluid and was co-operative at all times. He grew progressively weaker. At no time following operation was there any bowel movement, although repeated enemas were tried. The abdomen remained distended and tympanic. The wound drained constantly and showed no attempt to close. The urine showed a +++ test for albumin, and the sediment contained casts and a few red and white cells. The blood hemoglobin was 90 per cent and the red-cell count 4,590,000. The white-cell count was 7800. Two days after admission the blood sugar was 136, the nonprotein nitrogen 60 and the creatinine 29 mg per 100 cc. Twenty-four hours after operation the nonprotein nitrogen was 39 mg per 100 cc, and on the following day it was 35 mg per 100 cc. The white-cell count was 22,000. Six days later it was 36,200. On the thirty-third hospital day he was transferred to this hospital.

Physical examination showed the patient to be oriented and in only slight distress. The skin was warm and moist. The tongue was red and heavily coated. There was some bleeding about the gums. There were dullness and many bubbling rales at the right base. The abdomen showed slight tenderness. Peristalsis was normal. On the right side of the abdomen there was a large wound dehiscence, with viable bowel lateral to the rectus muscle. Two

stomas, one of the ileum and another of the colon, were thought to be identified. There was extensive undermining into the flank, with draining sinuses. The rectum was filled with barium.

The temperature was 100°F, and the pulse 92. The blood pressure was 95 systolic, 70 diastolic.

A review of the symptoms revealed that the patient had been accustomed to drinking a half to two bottles of beer a day for many years and that during the present illness he had drunk up to a pint of whisky a day. He had had no previous operations or serious illnesses. He usually had two or three bowel movements daily.

Two days after admission laboratory study revealed a serum nonprotein nitrogen of 35 mg per 100 cc, and the total protein was 6.41 gm, the albumin 3.85 gm, and the globulin 2.56 gm per 100 cc (albumin-globulin ratio, 1.5). The serum chloride was 84, the sodium 119.6, and the potassium 5.6 milliequiv per liter. The cephalin flocculation test was negative in twenty-four hours and \pm in forty-eight hours. The van den Bergh reaction was normal. The white-cell count was 23,200, the blood hemoglobin was 10.7 gm. The urine was negative for albumin. The prothrombin time was 19 seconds (normal, 16 seconds).

Roentgenograms of the chest and abdomen taken on the second hospital day showed plate-like atelectasis at the left base and some fluid in the left pleural cavity. There was no distention of the large or small bowel. There were remains of barium in the transverse colon and rectum. There was no definite evidence of free air beneath the diaphragm.

In the hospital the patient's condition became progressively worse. The chest became full of rales, and respiration was difficult. On the fourth hospital day the temperature suddenly rose to 103°F, and the white-cell count to 36,400. The abdomen was somewhat distended, although there were large quantities of fecal drainage. The following day a Harris tube, which had been passed the day before in preparation for a proposed ileotransverse colostomy, was found coiled in the stomach and withdrawn. Nearly all the gas had disappeared, and there appeared to be less abdominal distention. The next day a barium enema showed no obstruction as far as the hepatic flexure. The cecum and ascending colon could not be outlined. Examination of the blood at that time revealed a sodium of 130.7, chloride of 91, potassium of 3.3 and carbon dioxide of 30.5 milliequiv per liter. The fasting blood sugar was 87 mg per 100 cc. The white-cell count was 18,500, with 77 per cent neutrophils.

On the seventh hospital day the patient developed symptoms suggestive of delirium tremens with "shakes" and hallucinations. He became semidelirious and was incontinent of urine. The pulmonary situation became critical, with progressive respiratory embarrassment. There were coarse

rales and rhonchi over the entire chest. Repeated catheter suctioning of the tracheobronchial tree was productive of a large amount of thick, stringy, whitish, tenacious mucus.

On the tenth hospital day the temperature had risen to 105°F. The total protein was 5.8 gm per 100 cc, the amylase 22 units per 100 cc, and the carbon dioxide 26.9 and the chloride 100 milliequiv per liter. The calcium was 7.8, and the phosphorus 3.4 mg per 100 cc. The urine output dropped to 750 cc, and the nonprotein nitrogen rose to 60 mg per 100 cc. The patient was flushed and mildly cyanotic. The blood pressure was unobtainable. The pulse rate was 150, and the respirations 44.

The following morning, on the twelfth hospital day, the temperature had risen to 106°F, shortly after which the patient died.

DIFFERENTIAL DIAGNOSIS

DR MARSHALL K. BARTLETT: May we see the x-ray films?

DR STANLEY M. WYMAN: The original films of the chest show the left leaf of the diaphragm elevated, and there is horizontal linear density, which appears to lie chiefly in the region of the left lower lobe. There is no definite or significant fluid made out in the pleural space in the lateral view, but there is a suggestion of some blunting of the costophrenic angle in the posteroanterior view. The same day an upright film of the abdomen shows a gas-filled stomach at a considerable distance from what I take to be the diaphragm, and there is some suggestion of mottled rarefaction adjacent to the undersurface of the diaphragm. This is not definite but suggests gas in the space below the left leaf of the diaphragm. A film taken four days later shows essentially the same process, with atelectasis of the left lower lobe and a little more suggestion of fluid in the left costophrenic sinus. A film taken still later, at the time of barium-enema examination, shows no definite intrinsic lesion in the colon, but it does show a coiled tube in the stomach. Again, there is a suggestion of mottled rarefaction adjacent to the left leaf of the diaphragm, possibly lying below it. The last film of the chest shows essentially a progressive change, with atelectasis and probably fluid.

DR BARTLETT: Let us approach this problem by going back to the first admission to the outside hospital and see what the history seemed to be then and, putting that together with the operative findings, see if we can figure out any condition that will fit this picture. In the first hospital admission there was a history, going back approximately two months, of dull, crampy, epigastric pain, lasting a few minutes, occurring several times a day and relieved by two or three glasses of whisky. Then we have the statement that for many months he had a desire to defecate without success. Later in the history we are told that the normal bowel move-

ments were two or three a day. This may have represented a change in bowel habit. He went along like that until about a week before admission, when the pain became more severe, and he began drinking more to relieve it, without success. At that time he had nausea and vomiting of gastric contents. That is the only time in the story that he had nausea and vomiting. On admission the striking thing in the physical examination seemed to be that the abdomen was distended, the upper portion more so than the lower portion. For the first three days in the hospital he had a temperature of 99°F and a normal pulse. The white-cell count was normal until after operation, and then it rose to more than 20,000. At operation a normal appendix was found. However, the large bowel was distended, and a note was made that "the intestine showed acute enteritis." It is not specified whether this was the large or the small bowel. I assume, since it is a separate statement, that it refers to the small bowel. Its color was purple. What condition could produce that picture? The changes in bowel habit and the facts that at operation the colon was distended and that on barium enema the barium did not pass the hepatic flexure certainly bring to mind the possibility of an obstructing lesion in the large bowel. On the other hand, there are a good many things that seem hard to explain with that diagnosis. The location of pain during the two months before admission was epigastric. Certainly, lesions of the colon usually produce pain at a lower level than that. We are all probably familiar with the experimental work that Dr. Chester M. Jones did some years ago by distending balloons at various levels of the gastrointestinal tract to see where pain was produced in the abdomen. Distention of the hepatic or splenic flexure might produce pain in the right or left upper quadrant, but this epigastric pain is hard to explain on the basis of a lesion in the colon. It is also hard on that basis to explain the fact that the distention was limited to the upper abdomen, and the colostomy does not seem to have done any good, so I do not believe that an obstructing lesion of the colon fits the picture very well.

What lesion of the small bowel could he have had? Could it have been a tumor? A lesion like that should express itself either by obstruction or by bleeding. We have no evidence here that he had massive bleeding into the gastrointestinal tract. Could he have had an obstructing lesion in the small bowel? I think it would be very unlikely to have such a sudden change in the picture, with his mild symptoms becoming quite suddenly worse, unless we assume that the lesion perforated, but if such were the case, the findings at laparotomy would have been different. If he had a small-bowel obstruction, we would not expect the colon to be dilated and we would expect that both dilated and collapsed loops of small bowel would be found. So I do not believe that fits the picture very well.

It is noted that the bowel was almost purple. That suggests interference with blood supply. Could it have been a mesenteric thrombosis? I think that is unusual with such a gradual onset. Mesenteric thrombosis should have been a more acute picture, and I doubt if the outcome would have been so long drawn out.

Could this have been regional enteritis? Of course, the thing that brings that to mind is the fact that he developed a spontaneous small-bowel fistula where the colostomy was done, and since regional enteritis is notorious for forming fistulas, we must consider it. So far as the history is concerned, any change in the bowel habit has been in the direction of constipation rather than toward diarrhea. I think the pain could be consistent with an inflammatory lesion in the small bowel, but I rather expect that the description of the findings would be different at operation in that event. As we all know, regional enteritis is typically a fairly circumscribed or localized lesion. There may be multiple areas, but usually they do not cover a great extent of bowel in any one area. However, it is a possibility. I do not see how we can rule it out. Again, the distention, if due to a small-bowel lesion, would probably have been generalized and not limited, as this was, to the upper abdomen. Perhaps I am putting too much stress on that finding, but certainly it is emphasized in the history.

To move up the gastrointestinal tract — could this have been gall-bladder disease? It would be very atypical, and I do not believe the evidence fits the picture particularly well. It would not account for the changes in the small bowel at operation. The distention of the colon, perhaps, could have been purely secondary — that is, paralytic. Could this have been pancreatitis? I do not see how one can rule it out. It is unusual for pancreatitis to cause mild symptoms for a period of two months and then an acute attack. I would like that possibility better if this had come on suddenly, out of a clear sky. Pancreatitis typically occurs after a large meal or the ingestion of a considerable amount of liquor. This man drank quite a lot, but the onset was not typical. The normal amylase taken a month after the onset of the attack does not rule pancreatitis out at all. Typically, the amylase goes up in the first twenty-four or forty-eight hours and then comes down to normal. It could have come down long before this determination was

made and still that diagnosis could be the correct one.

How about acute gastritis? I should think it could produce the symptoms that he had up to the day he came into the hospital, — mild, dull, crampy, epigastric pain, — but it is hard to explain the development of acute, severe pain on the basis of simple gastritis.

How about an ulcer of the stomach or duodenum or possibly a gastric neoplasm that had perforated? I believe the history of the symptoms for two months before entry fits that reasonably well. I think the increase in pain for a week before admission could be explained on the basis of gastritis, the sudden, severe pain the day before admission representing a perforation. If we assume that it was one of those rare situations in which the perforation was into the lesser peritoneal cavity, which then became distended with air and fluid, we perhaps can explain the difference between the upper and lower abdominal distention. Could that explain the operative findings? If we do assume that he had perforation in the upper abdomen, even in the lesser peritoneal cavity, there probably would have been some leakage of irritating fluid into the general peritoneal cavity, resulting in generalized peritonitis, which might have caused the changes noted in the bowel. Distention of the large bowel we would assume on the basis of paralytic ileus, and the fact that colostomy did not work reinforces that thought. Was this an ulcer or a neoplasm? I cannot see any way to be sure of either. The patient was forty-eight and had a short history. It seems on a chance that it is more likely that he had ulcer than neoplasm, with perforation.

Accepting the situation as it was at operation, what happened from there on? It seems to me that it is all relatively simple: a small-bowel fistula developed. Why it developed I cannot be sure. If he had regional enteritis, that is reason enough in itself, or it is possible that in closing the wound in a distended patient, some injury was done to the bowel, which in the course of several days could have resulted in perforation. He developed a small-bowel fistula, wound sepsis, a great deal of loss of fluid and electrolytes from the small-bowel fistula, resulting in the imbalance in the blood chemistry that is outlined. Also, there seems to have been very little question that he had a septic process in the left upper quadrant under the diaphragm. There

is certainly a strong suggestion in the x-ray picture

A barium enema was then done. If this patient had a lesion of the upper abdomen, why did the barium enema fail to fill the right colon? I cannot answer that. I do not know whether it is safe to rule out an organic lesion in the hepatic flexure. I am inclined to do so and to say that this was something high up in the abdomen. The course was steadily downhill—a losing struggle against sepsis and a small-bowel fistula. The downhill course continued with progressive pulmonary difficulties. There was a thought at one time that ileotransverse colostomy could be done. That was probably on the basis of a rather desperate attempt to correct the fluid and electrolyte loss from the small bowel by short-circuiting the fistula and the colostomy. The patient was apparently not well enough to allow that to be done and went rapidly downhill and died. It seems that the downhill course was a mixture of sepsis, fluid and electrolyte loss, and pulmonary difficulties, with probably terminal bronchopneumonia.

CLINICAL DIAGNOSES

Wound dehiscence, with small-bowel fistulas
Chronic alcoholism, with delirium tremens
Bronchopneumonia

DR BARTLETT'S DIAGNOSES

Gastric ulcer, with perforation
Small-bowel fistulas
Bronchopneumonia

ANATOMICAL DIAGNOSES

Acute pancreatitis, with perforation of transverse colon and abscess formation
Peritoneal abscesses, with fat necrosis
Small-bowel fistulas
Operation colostomy
Pulmonary atelectasis
Pulmonary edema
Hepatomegaly, with fatty vacuolization
Acute splenitis with splenomegaly

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN At autopsy there was, as to be expected, a lot of sepsis around the

two colostomies that were present in the right lower abdomen. When the abdominal cavity was opened there was a gush of gas, the omentum was plastered down over the peritoneum and was thick and porky, suggesting long-standing sepsis. When that was elevated a relatively small pocket of pus in the right lower quadrant was broken into. It probably was secondary to three fistulas in that region. In lifting the transverse colon the examiner broke into a very large, greenish-black abscess, which involved the region of the hilus of the spleen and tail of the pancreas, and extended up under the left diaphragm, which corresponds to gas seen on the x-ray film. Surrounding this abscess and all over the omentum close by was a lot of chalky-white material characteristic of fat necrosis. Further dissection showed that the entire tail of the pancreas had become necrotic and that the pancreatic abscess had extended medially to involve the upper surface of the body and head of the pancreas. I should think that the entire process was probably due to a pancreatitis that perhaps started slowly and finally produced an overwhelming infection of the pancreas. The abscess had broken into the transverse colon, and that undoubtedly added to the sepsis and accounted for some of the gas that we saw on the film. There was no primary lesion in the stomach or any part of the colon. The small-bowel loops were matted together in the right lower quadrant, but only there. I do not understand the description, at the first operation in the other hospital, of the purplish bowel—unless some loop was strangulated at one time and then untwisted. We did not find anything like that, except the sepsis between the loops of bowel in the right lower quadrant.

DR BARTLETT Did you find any cause for the small-bowel fistula?

DR CASTLEMAN Nothing except the sepsis around the colostomy. He had a large, fatty liver (weighing 2700 gm), which might have been expected in a chronic alcoholic. The spleen was also enlarged (weighing 400 gm), but that may have been due, in part, to the sepsis. There was no fluid in either pleural cavity. Both lungs were pushed superiorly by the elevated diaphragm, and, in addition to the atelectasis, there was moderate pulmonary edema, but no foci of pneumonia.

MEDICAL PREPAREDNESS

TEN years ago there was much talk of medical preparedness, along with other kinds of preparedness for war. Activity that began at that time under the banner of preparedness has been almost continuous and has often been carried on by the same individuals or committees, but the word on the banner changed, first to *defense*, then to *victory* and then to *post-war planning*. Planning for what? Why, for preparedness, of course. So now it is beginning all over again, the world changes, but not the emotions of mankind!

In a recent Washington Report on the Medical Sciences it is stated that the "Army medical department is industriously gathering information on

establishment and operation of its own medical school." The statement makes it clear that nothing beyond the possible release of a few trial balloons is contemplated for the immediate present, but the idea of an Army medical school, as a means to an end, is worthy of careful consideration. In its favor would be the fact that once established, it would at least provide a group of men who had committed themselves to a career in military medicine. Although the number of such men could never provide sufficient personnel for wartime needs, it might well supply a nucleus round which civilian physicians would gather in times of emergency. It might also lead to an eventual recognition of the importance of military medicine among medical educators as a whole. On the other hand the Army's present plan of assigning a medical officer to the faculty of existing medical schools on a co-operative basis might be developed to give quicker and larger results, and at a lower unit cost to the Government.

All medical schools are today in a difficult financial position. For even the richest of universities the establishment of a new medical school is a major undertaking. An Army medical school would not be embarrassed regarding finances, however, even were it organized on a lavish scale it would be a trivial item on the federal budget. An Army school would be more apt to encounter difficulties in mustering an outstanding staff of teachers, such organization takes time, and in the matter of preparedness time again is of the essence. Unless it can be clearly seen that advantages will quickly flow, the project should not be advised.

Assuming that an adequate staff could be mustered within a period of two years and that it could be completely protected from political and other pressures (a *sine qua non* for success), it would be 1955 before the first class would emerge into anything useful from a medical point of view. An alumni body could not aggregate into useful volume before 1960 at the earliest, and the accumulation of that intangible thing called tradition, without which no institution can attain its maximum effectiveness, would lie still farther in the future.

It may be that the need is sufficiently urgent to consider initiating an Army medical school—

not to meet the present call for preparedness, but to prepare for the next time preparation may be called for. If there is reason to believe that the demand for military doctors is a long-range one that must be built into the national economy from this time forward, action should be taken. One cannot help feeling that the Army's medical record is a proud one as it stands, from Shippen to Bliss. Under these men and those who have served between them the Army has produced its Warrens, its Beaumonts and its Reeds. Could it have done so if it had been just another medical school? As one looks back over history one cannot help observing that the Medical Department of the Army has been conspicuously successful in extracting the best available talent from the profession as a whole when it was needed and in as sufficient volume as can ever be permitted by the exigencies of war.

TEACHING IN VETERANS ADMINISTRATION HOSPITALS

THE report on the practice and teaching of surgery in Veterans Administration hospitals, which appears elsewhere in this issue of the *Journal*, deserves careful reading and thoughtful consideration. There are several aspects of this matter that are closely tied with the socioeconomic problems of medicine today.

The execution of the plans formulated under General Hawley's tenure of office was, in large measure, the result of far-seeing policies envisioned by the late Dr. Elliott C. Cutler. The first and foremost goal was, and still is, the optimum care for the veterans in the Veterans Administration hospitals. That this primary purpose has, to a very gratifying extent, been accomplished is apparent from the report, and is clear and unmistakable to those who are associated with these "affiliated hospitals." To accomplish this, the most important step was to bring the hospitals in close connection with, and under the supervision of, the dean's committee of the various medical schools with which these hospitals are now affiliated; these dean's committees have, practically speaking, complete control of the appointment of the professional staff that serves the hospitals. The consultants, the attend-

ing surgeons and the resident staff must all be approved by the dean's committee before their names are sent to the administrative side for formal appointment. Thus, it has been possible to obtain a staff of well trained men of recognized surgical ability and with experience and interest in teaching. The selection of these men is now practically free from any political influence, however well intentioned that might be. The positions are given for professional merit alone. To quote the article: "In a word, they bring the medical school to the hospital." The senior consultants are men of known reputation as surgeons and teachers. The attending surgeons are younger, but, being free from administrative responsibilities, they do the bulk of the daily bedside and operating-room instruction. They handle the more difficult cases themselves, but, in general, their function in the operating room is to supervise and to assist personally the resident staff. To quote further, "It may be well to emphasize that the attending surgeon cannot be a man of limited experience hoping to broaden himself by operating in the Veterans Administration hospitals. He must be an accomplished surgeon, capable and willing to teach. His role is a comparatively selfless one." The presence of a well trained resident staff is a great asset to any hospital. Its advantages are obvious, and as the author of the article points out, the comparison between the hospital with the medical-school affiliation and that without one is most striking. That the care received by the patients in the affiliated hospitals is better admits of no argument. By proper utilization of the affiliated hospitals as teaching centers, great benefit comes to the patient. This policy has also provided a larger field for the proper training of the young surgeon. Both parties have benefited greatly.

What of the future? As long as the present policy continues, the patient in the Veterans Administration hospital will continue to receive a very high quality of care—as he should. But, as the author points out, such a system cannot be expanded too far without becoming administratively top-heavy, with disastrous results. "The machine would control the men, and the control of the patient would be in the grip of an automaton." But whatever

changes that lie ahead of us in the future, the medical profession cannot allow, through inertia or lack of interest, the actual professional care of patients in Veterans Administration hospitals drop to the low levels that were once the rule

THE MERRY WIDOW

GREER reports on another page in this issue of the *Journal* his experiences with victims of the double-barbed widow whose kiss is sometimes death. They are of more than passing interest, for this antiscidal vagrant, her egg sac flung over her back, for symbolic hourglass, its sands of time forever running out, stamped upon her ventral aspect, is readily widening her range even into those austere regions of New England north of Boston. *Latrodectus mactans*, despite her reputation, is neither sadistically merry nor brutally aggressive. Instead she is apparently a shy, timid and confused creature who kills her mate at the call of instinct rather than from sheer wantonness. She is more to be pitied than censured, for she seems doomed never to know the tranquil joys of domesticity. In view of the extreme toxicity of the venom with which she is armed, however, it is comforting to know that she attacks only when cornered, and to learn the effectiveness of calcium gluconate as an antidote for her bite.

NOTES FROM THE MEDICAL EXAMINER

IN THIS issue of the *Journal* a new department is initiated under the title "Notes from the Medical Examiner." It is the hope of the editors that this department, appearing at approximately monthly intervals, will meet with the approval of its readers and may be continued as long as it proves to be of value.

"Notes from the Medical Examiner" will be a department devoted to ground common to the specialist in legal medicine and to the clinician, whether specialist or general practitioner. It will include such matters as procedures and technical methods evolved from the study of cases terminating in the jurisdiction of the medical examiner's office, discussions of groups of cases ending fatally as a result of unpredictable deficiencies or hazards

in treatment or diagnosis, discussions of the legal and medical aspects of obscure and sudden deaths, and reviews of legal medical subjects, including toxicology, pathology and clinical subjects that are now dispersed in a variety of medical and other technical journals.

MASSACHUSETTS MEDICAL SOCIETY

VETERANS IN FOREIGN MEDICAL SCHOOLS

At the meeting of the Council held on October 6 a resolution (as printed in the December 2 issue of the *Journal*) disapproving a policy of the Veterans Administration advising veterans that they may attend foreign medical schools at the expense of the Government was unanimously adopted by the Council.

Copies of the resolution were sent to every Massachusetts senator and congressman. Each has received the following letter from the Veterans Administration concerning the problem:

Honorable Richard B. Wigglesworth
United States Representative
Milton, Massachusetts

Dear Mr. Wigglesworth:

This will acknowledge receipt of your letter of October 30, 1948 with which you enclosed a copy of a resolution adopted by the Council of the Massachusetts Medical Society relative to the approval by the Veterans Administration of medical schools located in foreign countries to provide training to American veterans of World War II, under the provisions of Public Law 346, 78th Congress, as amended.

The resolution has been read carefully and the contents thereof noted with interest. The statement contained in the resolution that "the Veterans Administration in Washington is advising veterans that they may attend any medical school in Europe at the expense of the Government, and . . ." is not consistent with the facts.

A copy of the *New England Journal of Medicine* was forwarded to the Veterans Administration by Dr. George C. Shattuck under date of July 29, 1948. Special attention was invited at that time to the editorial "Of Thee I Sing" and the reprint of a letter addressed to the editor by Dr. A. H. A. Campbell, 520 Commonwealth Avenue, Boston 15, Massachusetts, relative to the article by Dr. J. L. Lochner, Jr., Secretary of the Board of Registration for the State of New York, which appeared in the May 1, 1948, issue of the *Journal of the American Medical Association* entitled, "Licensure Evaluation of European Medical Graduates."

Dr. Shattuck was advised under date of August 24, 1948 that Public Law 346, 78th Congress as amended, provides in part that, "Such person (an eligible veteran) shall be eligible for and entitled to such course of education or training, full time or the equivalent thereof in part-time training, as he may elect, and at any approved educational or training institution at which he chooses to enroll, whether or not located in the State in which he resides, which will accept or retain him as a student

or trainee in any field or branch of knowledge which such institution finds him qualified to undertake or pursue" (Parenthetical statement added)

It was further emphasized in this connection that the Veterans Administration approved educational institutions to provide training under the above legislation. It does not accredit institutions, evaluate credits, or pass on the standards of one institution as compared with another. Every effort is made to approve only those institutions which are found to be qualified in accordance with the criteria established for approving educational institutions by the Veterans Administration. These criteria cover such factors as control, staff, plant and equipment, curriculum, finances, stability etc. Only in very exceptional cases are foreign educational institutions now approved which have been established subsequent to 1939.

With regard to the statement contained in the resolution that the Veterans Administration is advising veterans that they may attend any medical school in Europe, your constituents may be advised that it is the policy of the Veterans Administration to inform all veterans making inquiry concerning the possibility of pursuing medical training outside of the United States that most of the state boards of medical examiners, as well as the American Medical Association, have definite restrictions on recognition of work done in schools of medicine in foreign countries. They are informed that in more than a third of the states graduates of medical schools outside of the United States and Canada are not eligible for licensure. They are furnished with the list of eighteen states in which credentials from medical schools in foreign countries are not accepted, as shown in the *Journal of the American Medical Association*, May 13, 1945. Each inquiring veteran is informed that if he is planning to practice medicine in the United States, it is strongly advised that he check with the state board of medical examiners in the state in which he expects to practice, as to the acceptability of work from the foreign medical school which he has under consideration.

The Veterans Administration has had considerable correspondence with the Secretary of the American Medical Association relative to the matter of approval of foreign medical schools to provide training under Public Law 346. The Secretary recently furnished this office with several copies of a reprint from the *Journal of the American Medical Association*, May 17, 1947, Vol. 134, P. 278, "Requirements for Candidates for Medical Licensure on the Basis of Credentials Obtained in Countries Other Than the United States and Canada," and several copies of a directory of "Medical Examining and Licensing Boards" in the United States. Copies of this material have been furnished to each of the five offices of Attaches for Veterans Affairs located at the American Embassies, London, England, Paris, France, Rome, Italy, Mexico City, Mexico, and the American Consulate, Geneva, Switzerland. The Office of Attache for Veterans Affairs at London, has jurisdiction over Vocational Rehabilitation and Education matters in the United Kingdom, Eire, Norway, Sweden, and Denmark, the Attache at Paris has jurisdiction over France and Belgium, while the other Attaches have jurisdiction over such matters in the countries where they are located.

It may be of interest to your constituents to know that as of April 30, 1948, there were only 261 United States Veterans pursuing courses in the various fields of medicine in foreign countries under Public Law 346. Many of these veterans were pursuing postgraduate study in various specialized fields, having already obtained M.D. degrees. Fifty-five of the 261 were enrolled in approved schools in Canada. Forty-two of the number were pursuing training in England and Scotland. Four were enrolled in Ireland.

In conclusion it may be emphasized that it is not necessary for a veteran to inform the Veterans Administration that he intends to practice his profession in the United States or in a foreign country. In every instance where inquiry has been made of this office, the veteran has been alerted to the potential difficulties he must expect in securing license to practice in the United States. Therefore, in securing a medical education in a foreign country, veterans who consult us first do so of their own volition, and with full knowledge of the obstacles which

may make it impossible to practice their chosen profession in this country.

Please be assured that your interest in the welfare of veterans is very much appreciated.

O. W. CLARK

Executive Assistant Administrator

Veterans Administration

Under Public Law 346 the Veterans Administration, by implication, is constituted the approving authority for schools of all types. Since the Veterans Administration, according to Mr. Clark's letter, has consulted the American Medical Association "relative to" foreign medical schools, it is to be hoped that the approval of that organization, which is the acknowledged authority on medical schools, will be made a *sine qua non* of recognition of any medical institution by the Veterans Administration.

If Public Law 346 contains no criterion of minimal professional standards for courses in which veterans participate and if there is no stipulation regarding the value to the veteran of the knowledge and skill acquired, the law should be amended. It is questionable whether veterans should be permitted to take courses, at the taxpayers' expense, that will be worthless. When such a course is "chicken sexing," as pointed out in the editorial "Of Thee Sing," a waste of public money is all that is at stake but when study in unapproved medical schools is involved, the threat to acceptable medical standard in the United States is a matter of the gravest concern to physicians.

H. QUIMBY GALLUPE, *Secretary*

NOTES FROM THE MEDICAL EXAMINER

THE TOXICOLOGY OF ALCOHOL

No chemical known to man is responsible for so many deaths, lost manpower days and traumatic injuries as ethyl alcohol. It is directly or indirectly responsible for more than 50 per cent of all deaths caused by chemical agents.¹

Metabolism

Ethyl alcohol is completely absorbed from the gastrointestinal tract within one to three hours of ingestion. Its concentration after complete absorption is proportional to the water content of the individual tissue. Thus, the blood level provides a reliable index of that in brain tissue at all times in the postabsorptive period. The disappearance of alcohol from the body results from both oxidation and excretion (about 95 per cent by the former). Regardless of the dose, alcohol does not remain in the living body longer than twenty-four hours.

The oxidation probably does not exceed 5 to 10 gm. an hour or from 0.02-0.04 per cent an hour. The toxicity is purely that of an acute central-nervous-system depressant. A late manifestation of alcohol intoxication is a shift of water from an

intracellular to an extracellular situation,² a possible explanation for the thirst occurring during and after the alcoholic debauch

Alcohol as a Cause of Death

Alcohol may cause death either by acute narcosis or by initiating or accentuating physical and mental abnormalities in the patient and thus predisposing him to a variety of fatal misadventures³

Deaths due directly to alcoholism Ethyl alcohol is an anesthetic agent and in sufficient amounts kills by medullary paralysis. When death occurs relatively early in the postabsorptive phase (not the usual time for death) the blood alcohol concentration may be as high as 0.5 per cent or even higher. Frequently, death does not occur until several hours or longer after the onset of coma. Owing to continued metabolism, the post-mortem blood alcohol concentration may be well below 0.5 per cent. Alcoholic addicts frequently, by accident or design, take large doses of a barbiturate compound. There is an additive depressant action by these two anesthetic drugs.⁴ Complications of the alcoholic coma may be responsible for death, such as acute asphyxiation by food aspirated into the air passages or hemorrhagic pulmonary edema from the inhalation of liquid gastric juice. A series of alcoholic debauches may render the patient more susceptible to infection, particularly of a respiratory nature.

Hepatotoxic chemicals such as the halogenated hydrocarbons may be accentuated by acute and chronic alcoholism. The evidence to date does not specifically incriminate alcohol in the pathogenesis of liver cirrhosis except upon the basis of nutritional deficiency.⁵ Acute and chronic pancreatitis is said to be more common among alcoholic addicts,⁶ but this has not been our experience. The pathological nervous-system change in chronic alcoholism is obscure except in relation to deficiency diseases—for example, Wernicke's disease⁷ and polyneuritis. Fatal circulatory collapse may develop unpredictably and uncontrollably in acute delirium tremens related perhaps to the severe physical overexertion. In several cases severe hyperthermia of undetermined cause has been observed as a terminal event.

Deaths due indirectly to acute alcoholism Predisposition to misadventure accounts for more deaths than the direct pharmacologic effect. Fully 50 per cent of drivers and nearly one third of pedestrians involved in fatal accidents are termed to have been "under the influence."⁹ It is not unusual for the inebriate to commit suicide—an act that he would probably not have consummated in his alcohol-free moments. About 50 per cent of persons homicidally slain had been drinking, according to the case records of the Department of Legal Medicine of Harvard Medical School. Obviously, it may be of great legal importance to know whether the perpetrator or victim of violence

was under the influence of alcohol and the degree of that influence.

Levels of Intoxication in Relation to Blood Alcohol Concentration

Most people show definite and obvious signs of intoxication at 0.25 per cent, a level requiring in the average adult the ingestion of approximately 12 ounces of whisky or the equivalent within a few hours. Although many persons show evidence of intoxication at lower blood levels, few, if any, fail to have obvious impairment of physical and mental faculties at concentrations higher than 0.25 per cent. High dilution of the alcohol beverage or food in the stomach may unpredictably lower the absorption rate. Those accustomed to drinking often show less severe outward manifestations of ingestion than the occasional drinker or the neophyte. Coma approximating surgical anesthesia is reached usually at levels of 0.4 per cent or above.

The National Safety Council has adopted the concentration 0.15 per cent alcohol in the blood as *prima facie* evidence of intoxication with respect to the operation of a motor vehicle. At this concentration not all people (perhaps 50 per cent) show significant behavior alterations on casual examination. In Evanston, Illinois, drivers with more than 0.15 per cent alcohol in the blood were fifty-five times more likely to become involved in a personal-injury accident than drivers with no alcohol.⁹

Specificity

With practically all present-day methods, alcohol is determined indirectly by estimation of the volatile reducing material of the specimen by distillation or by desiccation.¹⁰ In the presence of putrefaction, analysis is unreliable because of the formation of incompletely identified volatile reducing substances. Since liver tissue oxidizes alcohol after death, it should not be used.

or trainee in any field or branch of knowledge which such institution finds him qualified to undertake or pursue" (Parenthetical statement added)

It was further emphasized in this connection that the Veterans Administration approved educational institutions to provide training under the above legislation. It does not accredit institutions, evaluate credits, or pass on the standards of one institution as compared with another. Every effort is made to approve only those institutions which are found to be qualified in accordance with the criteria established for approving educational institutions by the Veterans Administration. These criteria cover such factors as control, staff, plant and equipment, curriculum, finances, stability etc. Only in very exceptional cases are foreign educational institutions now approved which have been established subsequent to 1939.

With regard to the statement contained in the resolution that the Veterans Administration is advising veterans that they may attend any medical school in Europe, your constituents may be advised that it is the policy of the Veterans Administration to inform all veterans making inquiry concerning the possibility of pursuing medical training outside of the United States that most of the state boards of medical examiners, as well as the American Medical Association, have definite restrictions on recognition of work done in schools of medicine in foreign countries. They are informed that in more than a third of the states graduates of medical schools outside of the United States and Canada are not eligible for licensure. They are furnished with the list of eighteen states in which credentials from medical schools in foreign countries are not accepted, as shown in the *Journal of the American Medical Association*, May 13, 1945. Each inquiring veteran is informed that if he is planning to practice medicine in the United States, it is strongly advised that he check with the state board of medical examiners in the state in which he expects to practice, as to the acceptability of work from the foreign medical school which he has under consideration.

The Veterans Administration has had considerable correspondence with the Secretary of the American Medical Association relative to the matter of approval of foreign medical schools to provide training under Public Law 346. The Secretary recently furnished this office with several copies of a reprint from the *Journal of the American Medical Association*, May 17, 1947, Vol 134, P 278, "Requirements for Candidates for Medical Licensure on the Basis of Credentials Obtained in Countries Other Than the United States and Canada," and several copies of a directory of "Medical Examining and Licensing Boards" in the United States. Copies of this material have been furnished to each of the five offices of Attaches for Veterans Affairs located at the American Embassies, London, England, Paris, France, Rome, Italy, Mexico City, Mexico, and the American Consulate, Geneva, Switzerland. The Office of Attache for Veterans Affairs at London, has jurisdiction over Vocational Rehabilitation and Education matters in the United Kingdom, Eire, Norway, Sweden, and Denmark, the Attache at Paris has jurisdiction over France and Belgium, while the other Attaches have jurisdiction over such matters in the countries where they are located.

It may be of interest to your constituents to know that as of April 30, 1948, there were only 261 United States Veterans pursuing courses in the various fields of medicine in foreign countries under Public Law 346. Many of these veterans were pursuing postgraduate study in various specialized fields, having already obtained M.D. degrees. Fifty-five of the 261 were enrolled in approved schools in Canada. Forty-two of the number were pursuing training in England and Scotland. Four were enrolled in Ireland.

In conclusion it may be emphasized that it is not necessary for a veteran to inform the Veterans Administration that he intends to practice his profession in the United States or in a foreign country. In every instance where inquiry has been made of this office, the veteran has been alerted to the potential difficulties he must expect in securing license to practice in the United States. Therefore, in securing a medical education in a foreign country, veterans who consult us first do so of their own volition, and with full knowledge of the obstacles which

may make it impossible to practice their chosen profession in this country.

Please be assured that your interest in the welfare of veterans is very much appreciated.

O. W. CLARK
Executive Assistant Administrator
Veterans Administration

Under Public Law 346 the Veterans Administration, by implication, is constituted the approving authority for schools of all types. Since the Veterans Administration, according to Mr. Clark's letter, has consulted the American Medical Association "relative to" foreign medical schools, it is to be hoped that the approval of that organization, which is the acknowledged authority on medical schools, will be made a *sine qua non* of recognition of any medical institution by the Veterans Administration.

If Public Law 346 contains no criterion of minimal professional standards for courses in which veterans participate and if there is no stipulation regarding the value to the veteran of the knowledge and skill acquired, the law should be amended. It is questionable whether veterans should be permitted to take courses, at the taxpayers' expense, that will be worthless. When such a course is "chicken sexing," as pointed out in the editorial "Of Thee I Sing," a waste of public money is all that is at stake, but when study in unapproved medical schools is involved, the threat to acceptable medical standards in the United States is a matter of the gravest concern to physicians.

H. QUIMBY GALLUPE, Secretary

NOTES FROM THE MEDICAL EXAMINER THE TOXICOLOGY OF ALCOHOL

No chemical known to man is responsible for so many deaths, lost manpower days and traumatic injuries as ethyl alcohol. It is directly or indirectly responsible for more than 50 per cent of all deaths caused by chemical agents.¹

Metabolism

Ethyl alcohol is completely absorbed from the gastrointestinal tract within one to three hours of ingestion. Its concentration after complete absorption is proportional to the water content of the individual tissue. Thus, the blood level provides a reliable index of that in brain tissue at all times in the postabsorptive period. The disappearance of alcohol from the body results from both oxidation and excretion (about 95 per cent by the former). Regardless of the dose, alcohol does not remain in the living body longer than twenty-four hours.

The oxidation probably does not exceed 5 to 10 gm an hour or from 0.02-0.04 per cent an hour. The toxicity is purely that of an acute central-nervous-system depressant. A late manifestation of alcohol intoxication is a shift of water from an

be demonstrated in the sputum. All this and much more has come to be known as associated with the personality of the author.

The reviewer hoped that in this new book he would find some of the newer aspects of pathology, diagnosis and treatment that belong to the 1948 era. He looked for longer discussion of tuberculous bronchitis, its implications regarding the dynamics of cavities or the effect of bronchial stenosis on the clinical course of the disease.

The author devotes considerable space to outdoor and light treatment as well as tuberculin therapy, but gives very little detailed discussion on the indications and mode of treatment with streptomycin.

The term "compression therapy" hardly has a place in a modern book on tuberculosis, and yet it is quite loosely used together with "collapse therapy." The two are certainly not synonymous any more than two other terms — phrenicectomy and phrenicotomy — that are used indiscriminately.

Since lobectomy and pneumonectomy have a place in the general scheme of tuberculosis therapy and since this type of treatment requires the greatest experience and clinical judgment, the reader has a right to expect much more guidance on this subject than the few paragraphs allotted to it in this book.

Certainly, the author is still the great scholar and the great interpreter of phthisiogenesis with its multifiform pathologic lesions and the effect it has on the clinical course of the disease. His description of the neurologic manifestations of pulmonary tuberculosis is a gem and a classic.

Knowing therefore the erudition and the long experience of the author one expects an authoritative as well as an up-to-date treatise of the subject. Instead, this book is merely another edition of his old books.

Atlas of Plastic Surgery. By Morton I. Berson, M.D. 4th cloth, 304 pp., illustrated. New York: Grune and Stratton, 1948. \$15.00.

There is probably no branch of surgery that can be better described in pictorial form than plastic surgery, mainly because it consists of the treatment of surface deformities. This book is divided into eight chapters. The first covers a general discussion of the various standard procedures in the plastic repair of wounds. The remaining chapters consider the operative procedures in the correction of the various deformities of the face, with the exception of Chapter VII which deals with mammoplasties and lipectomies. The cosmetic aspect of facial malformations is described in more detail than conditions associated with faulty function. This book of 304 pages is well illustrated with numerous diagrams and photographs.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Practical Bacteriology, Hematology, and Parasitology. By E. R. Stitt, M.D., Ph.M., Sc.D., LL.D., graduate of the London School of Tropical Medicine, Paul W. Clough, M.D., physician-in-charge of the Diagnostic Clinic, Johns Hopkins Hospital, and assistant professor of medicine, Johns Hopkins University School of Medicine, and associate professor of medicine, University of Maryland School of Medicine, and Sara E. Branham, M.D., Ph.D., Sc.D., senior bacteriologist, National Institute of Health, professional lecturer in preventive medicine, George Washington University School of Medicine, and chairman, Laboratory Section, American Public Health Association, 1946-1947 and contributors. Tenth edition. 8^{vo}, cloth, 991 pp., with 765 illustrations and 7 color plates. Philadelphia: The Blakiston Company, 1948. \$10.00.

This standard work has been thoroughly revised to bring it up to date since the publication of the last edition. The text is well printed with a legible type on light paper. A com-

prehensive index concludes the volume. Certain reference tables have been printed on the back and front covers. This is a bad practice, since they will become defaced through usage. The book is recommended for all medical libraries and all persons interested in the subject.

Paediatrics for Nurses. By Arthur G. Watkins, M.D., F.R.C.P., physician in children's diseases, Cardiff Royal Infirmary and lecturer in pediatrics, Welsh National School of Medicine. 12^{vo} cloth, 192 pp., with 22 illustrations and 9 tables. Baltimore: The Williams and Wilkins Company, 1948. \$3.50.

This manual is essentially clinical in its approach and stresses medicinal therapy. Material on nursing technique and on the infectious fevers is omitted. Printed in Great Britain, the manual reflects the British point of view.

Victor Robinson Memorial Volume: Essays on history of medicine in honor of Victor Robinson on his sixtieth birthday August 16, 1946. Solomon R. Hagan, M.D., editor. 8^{vo}, cloth, 447 pp., with 38 illustrations. New York: Froben Press, Incorporated, 1948. \$10.00.

This memorial volume was intended for Dr. Victor Robinson on his sixtieth birthday, but owing to unavoidable delays it was not published until after his death in January, 1947. There are thirty-eight contributions by physicians and others interested in the history of medicine, together with a number of memorial sketches. A great many of them are biographic. The following may be noted as of special interest: "Job's Disease," by David I. Vachet, the noted historian of Jewish medicine; the biographic sketch of Julius Leopold Pagel of London, the history of the *United States Pharmacopeia*, by George Urdang, and "Jewish Medical Historians," by Dr. Harry A. Savitz, of Boston. The edition is limited to 350 copies. The volume should be in all medical-history collections.

Successful Marriage: An authoritative guide to problems related to marriage from the beginning of sexual attraction to matrimony and the successful rearing of a family. Edited by Morris Fishbein, M.D., and Ernest W. Burgess, Ph.D., professor and chairman, Department of Sociology, University of Chicago. 8^{vo} cloth, 547 pp., with 16 illustrations and 3 tables. Garden City: Doubleday and Company, 1947. \$4.50.

This comprehensive work by many authors on all phases of marriage, and problems relating thereto constitutes an encyclopedia on the subject. The text is divided into five parts: preparation for marriage, marriage, conception, pregnancy and childbirth, the child in the family, and social problems of sex in marriage.

The text is well written, showing good editorship. The printing is done with good type on lightweight paper. The work is intended for prospective brides and bridegrooms and their parents, but because of certain chapters on sexual technique and the prevention of conception, the book should not be available to adolescents. The last-named chapter probably makes the book illegal in Massachusetts under present state laws.

Widening Horizons in Medical Education: A study of the teaching of social and environmental factors in medicine, 1945-1946. (A report of the joint committee of the Association of American Medical Colleges and the American Association of Medical Social Workers.) 8^{vo}, cloth, 228 pp. New York: The Commonwealth Fund, 1948. \$2.75.

The general aims of this study were fourfold: to gather information on present-day teaching of the social and environmental aspects of medicine in the United States and Canada, to analyze the data obtained, to evaluate the methods and techniques of instruction in use, and to offer recommendations based on conclusions drawn from the study.

The Committee considers its report as an initial probing of the subject and recommends further study along special lines by professional organizations and other interested groups, and the individual medical study and evaluation of methods and techniques in this phase of teaching. The

COMMENT

Those diseases above the seven-year median are chicken pox, diphtheria, measles, mumps and tuberculosis all forms.

Those diseases with incidence below the seven-year median are bacillary dysentery, poliomyelitis, salmonellosis, scarlet fever, typhoid fever, undulant fever and whooping cough.

Chicken pox for the second month in succession is highest since beginning of reporting in 1916.

For the eighth month, mumps has the highest incidence since it was made reportable in 1916.

Diphtheria has the highest incidence since 1934, and measles the highest since 1925.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anthrax was reported from Saugus, 1, total, 1.

Diphtheria was reported from Abington, 1; Arlington, 2; Boston, 18; Brockton, 1; Chelsea, 1; Dartmouth, 1; Framingham, 1; Gardner, 1; Lowell, 1; North Attleboro, 1; North Reading, 1; Somerville, 1; Waltham, 3; Winchester, 3; Winthrop, 1, total, 37.

Dysentery, bacillary, was reported from Lowell, 2; Medford, 1, total, 3.

Encephalitis, infectious, was reported from Millbury, 1; Pittsfield, 2; Worcester, 2, total, 5.

Lymphocytic choriomeningitis was reported from Barnstable, 1, total, 1.

Malaria was reported from Wellesley, 1, total, 1.

Meningitis, meningococcal, was reported from Boston, 1; Needham, 1; Spencer, 1, total, 3.

Meningitis, Pfeiffer-bacillus, was reported from Chicopee, 1; Lynn, 1; Pittsfield, 1; Saugus, 1, total, 4.

Meningitis, pneumococcal, was reported from Boston, 1; Northbridge, 1; Springfield, 2, total, 4.

Meningitis, other forms, was reported from Boston, 1, total, 1.

Meningitis, undetermined, was reported from Auburn, 1; Springfield, 1, total, 2.

Poliomyelitis was reported from Peabody, 1; Springfield, 1; Stoneham, 1; Worcester, 2, total, 5.

Salmonellosis was reported from Brookline, 1; Medford, 1; Wakefield, 1, total, 3.

Septic sore throat was reported from Boston, 6; Fall River, 1; Merrimac, 1, total, 8.

Trachoma was reported from Worcester, 1, total, 1.

Trichinosis was reported from Everett, 1; Fall River, 1; Gloucester 1; Hingham, 1, total, 4.

Typhoid fever was reported from Quincy, 1, total, 1.

Undulant fever was reported from Dartmouth, 1; Plymouth, 1, total, 2.

MISCELLANY

SEED FOR EUROPE

Two CARE seed packages containing potential harvest of food for human beings and fodder for livestock in Europe are now available for shipment.

Thirty-one selected varieties of vegetable seeds, enough to plant a garden up to 50 by 150 feet, are contained in the package designed for family use. The other, weighing 70 pounds, holds enough hybrid field corn seed to plant $2\frac{1}{2}$ acres and provide valuable feed for fattening meat animals or maintaining a high level of production in dairy cattle.

The new CARE packages are being offered for \$4 each, and orders are now being received by CARE at 50 Broad Street, New York 4, New York, as well as at all CARE offices throughout the country, for guaranteed delivery in eleven European countries. Orders should be sent at the earliest possible date to ensure delivery in time for the planting seasons.

The new packages may be ordered for delivery in Austria, Belgium, Czechoslovakia, Finland, Italy, France, Greece, the Netherlands, Poland, Great Britain (England, Scotland, Wales and Northern Ireland) and the American, British and French zones of Germany and Berlin.

CORRESPONDENCE

PROPER USE OF HOSPITALS

To the Editor: I should like to invite attention to the editorial in the *Norfolk Medical News* for November, 1948 especially the following quotation:

Numerous surveys have shown

6. Failure of hospital management to limit admissions to patients requiring hospital treatment.

7. Failure of physicians to cease hospitalizing patients who might adequately be cared for at home.

8. Tendency of physicians to continue employment of unnecessary laboratory procedures and expensive treatments.

A concerted effort by both management and physicians will show effective result.

I have for some time been convinced that the major effort in the solution of this is right in the lap of the doctors of the hospital staff. If they fail to take the initiative before some body else does, they will have missed a major opportunity. It seems to me that finding No. 8 presents the chief challenge. Teaching hospitals have more reason perhaps to continue present practice, but a very desirable and far reaching reform could be initiated by making students, interns and residents (and the visiting staff too) conscious that some body has to pay the costs and that this is one of the items of medical expense about which something can be done.

Is there anything in medical socioeconomics that is more important?

ELMER S. BAGWELL, M.D., Chairman

Committee on Medical Economics
Massachusetts Medical Society

BOOK REVIEWS

Tuberculosis: A discussion of pathogenesis, immunology, pathologic physiology, diagnosis, and treatment. By Francis M. Pottenger, M.A., M.D., LL.D. 8°, cloth, 597 pp., with 103 illustrations. St. Louis: The C. V. Mosby Company, 1948. \$12.00.

Those who have been brought up in the field of tuberculosis have come to know what to expect from the writings of the senior Dr. Pottenger. For nearly fifty years he has been an advocate of tuberculin therapy in pulmonary tuberculosis. He has written extensively on the importance of a very meticulous physical examination, extolling especially the fine points of inspection and palpation in the diagnosis of pulmonary tuberculosis. In fact, he claims to be able to diagnose pulmonary tuberculosis by palpation long before there is activity in the lungs and before tubercle bacilli can

he demonstrated in the sputum. All this and much more has come to be known as associated with the personality of the author.

The reviewer hoped that in this new book he would find some of the newer aspects of pathology, diagnosis and treatment that belong to the 1948 era. He looked for longer discussion of tuberculous bronchitis, its implications regarding the dynamics of cavities or the effect of bronchial stenosis on the clinical course of the disease.

The author devotes considerable space to outdoor and light treatment as well as tuberculin therapy, but gives very little detailed discussion on the indications and mode of treatment with streptomycin.

The term "compression therapy" hardly has a place in a modern book on tuberculosis, and yet it is quite loosely used together with "collapse therapy." The two are certainly not synonymous any more than two other terms — phrenicectomy and phrenicotomy — that are used indiscriminately.

Since lobectomy and pneumonectomy have a place in the general scheme of tuberculosis therapy and since this type of treatment requires the greatest experience and clinical judgment, the reader has a right to expect much more guidance on this subject than the few paragraphs allotted to it in this book.

Certainly, the author is still the great scholar and the great interpreter of phthisiogenesis with its multiform pathologic lesions and the effect it has on the clinical course of the disease. His description of the neurologic manifestations of pulmonary tuberculosis is a gem and a classic.

Knowing therefore the erudition and the long experience of the author one expects an authoritative as well as an up-to-date treatise of the subject. Instead, this book is merely another edition of his old books.

Atlas of Plastic Surgery. By Morton I. Berson, M.D., 4th ed., cloth, 304 pp., illustrated. New York: Grune and Stratton, 1948. \$15.00.

There is probably no branch of surgery that can be better described in pictorial form than plastic surgery, mainly because it consists of the treatment of surface deformities. This book is divided into eight chapters. The first covers a general discussion of the various standard procedures in the plastic repair of wounds. The remaining chapters consider the operative procedures in the correction of the various deformities of the face, with the exception of Chapter VII, which deals with mammoplasties and lipectomies. The cosmetic aspect of facial malformations is described in more detail than conditions associated with faulty function. This book of 304 pages is well illustrated with numerous diagrams and photographs.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Practical Bacteriology, Hematology, and Parasitology. By E. R. Stitt, M.D., Ph.D., Sc.D., LL.D., graduate of the London School of Tropical Medicine, Paul W. Victor Robinson Memorial Volume: Essays on history of medicine in honor of Victor Robinson on his sixtieth birthday, August 16, 1946. Solomon R. Kagan, M.D., editor, 8^{vo}, cloth, 447 pp., with 38 illustrations. New York: Froben Press, Incorporated, 1948. \$10.00.

This memorial volume was intended for Dr. Victor Robinson on his sixtieth birthday, but owing to unavoidable delays it was not published until after his death in January, 1947. There are thirty-eight contributions by physicians and others interested in the history of medicine, together with a number of memorial sketches. A great many of them are biographic. The following may be noted as of special interest: "Job's Disease," by David I. Macht, the noted historian of Jewish medicine; the biographic sketch of Julius Leopold Pagel, of London, the history of the *United States Pharmacopoeia*, by George Urdang, and "Jewish Medical Historians," by Dr. Harry A. Savitz, of Boston. The edition is limited to 350 copies. The volume should be in all medical-history collections.

Successful Marriage: An authoritative guide to problems related to marriage from the beginning of sexual attraction to matrimony and the successful rearing of a family. Edited by Morris Fishbein, M.D., and Ernest W. Burgess, Ph.D., professor and chairman, Department of Sociology, University of Chicago. 8^{vo}, cloth, 347 pp., with 16 illustrations and 3 tables. Garden City: Doubleday and Company, 1947. \$4.50.

This comprehensive work by many authors on all phases of marriage, and problems relating thereto constitutes an encyclopedia on the subject. The text is divided into five parts: preparation for marriage, marriage, conception, pregnancy and childbirth, the child in the family, and social problems of sex in marriage.

The text is well written, showing good editorship. The printing is done with good type on lightweight paper. The work is intended for prospective brides and bridegrooms and their parents, but because of certain chapters on sexual technique and the prevention of conception the book should not be available to adolescents. The last-named chapter probably makes the book illegal in Massachusetts under present state laws.

Widening Horizons in Medical Education: A study of the teaching of social and environmental factors in medicine, 1945-1946. (A report of the joint committee of the Association of American Medical Colleges and the American Association of Medical Social Workers.) 8^{vo}, cloth, 228 pp. New York: The Commonwealth Fund, 1948. \$2.75.

The general aims of this study were fourfold: to gather information on present-day teaching of the social and environmental aspects of medicine in the United States and Canada, to analyze the data obtained, to evaluate the methods and techniques of instruction in use, and to offer recommendations based on conclusions drawn from the study.

The Committee considers its report as an initial probing of the subject and recommends further study along special lines by professional organizations and other interested groups, and the individual medical study and evaluation of methods and techniques in this phase of teaching. The

Committee is convinced that medical social teaching is undergoing rapid change and growth. The report is recommended for all medical libraries, medical schools and interested persons.

Control of Pain with Saddle Block and Higher Spinal Anesthesia. Edited by J. H. Walton, M.D. 8°, paper, 52 pp., with 5 illustrations and 12 plates. Summit, New Jersey: Ciba Pharmaceutical Products, Incorporated, 1948.

This short monograph presents the technics of spinal anesthesia in obstetrics and surgery, including abdominal section, with an additional chapter on nupercaine. The color plates are well done and effectively illustrate the text. The small volume should prove interesting to obstetricians and surgeons.

Children's Eye Nursing. By James H. Doggart, M.A., M.D. (Cantab.), F.R.C.S., Eng., ophthalmic surgeon, Hospital for Sick Children, Great Ormond Street, London, surgeon, Moorfields Eye Hospital, ophthalmic surgeon, St. George's Hospital, and lecturer in ophthalmology at St. George's Hospital Medical School. 12°, cloth, 144 pp., with 93 illustrations and 4 color plates. London: Henry Kimpton, 1948. 9/6 net.

This manual has been written for nurses. The material is well organized, and the text well written. The publishing is excellent. The manual should prove useful to all nurses.

Nature of Life. A study on muscle. By A. Szent-Györgyi, Department of Biochemistry, University, Budapest. 8°, cloth, 91 pp., with 22 illustrations and 7 plates. New York: Academic Press, Incorporated, 1948. \$3.00.

This small volume contains a series of lectures delivered by Dr. Szent-Györgyi at the University of Birmingham and the Massachusetts Institute of Technology. The lectures summarize the work done in the author's laboratory and discuss the histologic, molecular and electronic structure of muscle myosin and actin, actomyosin and the muscle fiber.

The Clinical Picture of Thyrotoxicosis. By Peter McEwan, M.A., M.B., Ch.B., F.R.C.S. (Edin). 8°, cloth, 127 pp., with 4 plates and 5 tables. Edinburgh: Oliver and Boyd, 1948. 15s. net.

This monograph on toxic goiter has been written principally for the general practitioner, and emphasis has been placed on the clinical aspects of the disease. Thirty-one case histories have been interpolated throughout the text. The plate work is good, and the publishing is excellent. The small volume should prove interesting to physicians interested in the subject. It is pleasing to witness the return of high-class publishing in Great Britain.

Progress in Neurology and Psychiatry. An annual review. Volume III. Edited by E. A. Spiegel, M.D., professor and head, Department of Experimental Neurology, Temple University School of Medicine, Philadelphia. 8°, cloth, 661 pp. New York: Grune and Stratton, 1948. \$10.00.

In this third volume of a standard annual, over 2800 papers have been revised. Chapters have been added on mental deficiency and criminal psychiatry. Bibliographies are appended to the various chapters. The printing and type are excellent. A lighter paper could have been used to advantage. The series is recommended for all medical libraries and as a reference work to neurologists and psychiatrists.

NOTICES

ANNOUNCEMENTS

Dr. Raymond Gelfman announces the removal of his office to 83 Maple Street, Springfield.

Dr. James A. Halsted announces that his office is now at the Faulkner Hospital, Jamaica Plain, Boston.

Dr. Paul Graves Myerson announces the removal of his office to 1093 Beacon Street, Brookline.

GEORGE F. BAKER CLINIC

The Committee on Diabetes, appointed by action of the Massachusetts Medical Society, has suggested that clinical exercises in diabetes be offered without charge in various hospitals for physicians. To this end the George F. Baker Clinic at the New England Deaconess Hospital offers exercises on Monday and Friday of each week. The schedules are as follows:

Monday, 8:00-9:00 a.m., Second Floor, New England Deaconess Hospital. Case Presentations in Diabetes and Surgery of the Extremities.

Friday, 8:00-8:15 a.m. Second Floor, New England Deaconess Hospital. X-Ray Pathology in Diabetes. 8:15-9:00 a.m. Classroom, George F. Baker Building. Case Problems in Treatment of Diabetes and Complications. Pregnancies, acidosis, insulin resistance and so forth.

9:00-10:30 a.m. Medical Rounds for Visiting Physicians.

9:00-10:30 a.m. Instruction in Diet and Urine Testing (for Office Nurses, Technicians or Secretaries Sent by Physicians).

10:30-11:15 a.m. Class Teaching in Diabetes (Physicians, Office Assistants and Nurses are welcome).

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of Building D, Harvard Medical School, on Tuesday, January 11 at 8:00 p.m. The chairman for the evening is Dr. Raymond D. Adams.

PROGRAM

The Correlation between Morphologic and Functional Disorders in the Motor-Nerve Cells in Poliomyelitis. Derek E. Denny-Brown and Joseph M. Foley.

An Encephalomyelitic Virus of Mice Causing Demyelinating Lesions of the Central Nervous System. F. Sargent Cheever, O. T. Bailey and A. M. Pappenheimer.

Pathological Changes in Carbon Monoxide Poisoning. Charles S. Kubik.

Subsequent meetings will be held on February 8, March 8, April 12 and May 10.

MEDICAL SOCIETY OF THE STATE OF NEW YORK

The annual meeting of the Medical Society of the State of New York will be held at the Hotel Statler, Buffalo, from May 2 to 5, inclusive.

A CLINICAL AND EXPERIMENTAL STUDY OF ISUPREL IN SPONTANEOUS AND INDUCED ASTHMA

FRANCIS C. LOWELL, M.D.,* JOHN J. CURRY, M.D.,† AND IRVING W. SCHILLER, M.D.‡

BOSTON

ONE of the synthetic analogues of epinephrine — 1-(3, 4-dihydroxyphenyl)-2-isopropylaminoethanol — has been studied under the name of aleudrin for a number of years in Europe. The experimental and clinical use of this drug in bronchial asthma and emphysema has been reviewed by Dautrebande,¹ and a report has been published in this country by Charlier.² The drug, administered as an aerosol, has been described as being especially effective in relieving attacks of bronchial asthma and significantly more active than epinephrine.

In this country Segal³ has reported excellent results in the treatment of bronchial asthma with the same preparation, also called isuprel, and Siegmund et al.⁴ found this drug to be the most active of a number of structurally related compounds in a study in guinea pigs using histamine and horse serum.

We have had occasion to observe the efficacy of isuprel in asthmatic patients in the outpatient clinic, among private patients on the hospital wards and also in association with experimental studies involving the induction of asthma-like attacks with histamine, acetyl-beta-methyl choline (methacholine) and certain allergenic extracts.

MATERIALS AND METHODS

Methacholine was injected intramuscularly in a concentration of 10 mg per cubic centimeter, and histamine acid phosphate was injected intravenously in a concentration of 0.2 mg per cubic centimeter. Allergenic extracts were prepared in phosphate buffer at a reaction of pH 7.4 containing 0.5 per cent phenol in a concentration of 1.20 by weight of dry pollen.

‡Instructor in medicine, Boston University School of Medicine; member Allergy Clinic, Massachusetts Memorial Hospitals.

Isuprel§ was made available to us as a solution for administration by aerosol in a concentration of 1 and 0.5 per cent, in a concentration of 0.02 and 0.01 per cent for injection, and in tablets containing 10 mg for sublingual administration. The effectiveness of these preparations in relieving the signs and symptoms in asthmatic subjects was studied by the following methods.

Asthmatic subjects using this agent were observed for relief of asthma on the hospital wards or at home. The effectiveness of treatment was judged chiefly by statements made by the patients and to a lesser extent by changes in physical signs. The use of other preparations was not specifically discouraged, and there were frequent cases in which the efficacy of isuprel could be compared with that of other agents with which the patient was familiar.

Subjects with asthma were observed in the laboratory during spontaneous attacks, and changes in vital capacity and physical signs, as well as the degree of subjective relief, were observed after the administration of isuprel.

Similar observations were made in asthma-like attacks induced by exposure to aerosolized allergenic extracts, histamine and methacholine and by injections of histamine and methacholine according to technics that have been described elsewhere.^{5, 6}

The vaponephrin nebulizer or the No. 40 DeVilbiss nebulizer was used with a hand bulb by patients treating their asthmatic attacks outside the hospital, and these nebulizers supplied with pressure from an oxygen tank with the flow meter adjusted to read 6 to 8 liters per minute were also used on the ward and in the laboratory. Although the No. 40 DeVilbiss nebulizer may be somewhat less efficient than the vaponephrin nebulizer,⁷ we observed no difference between the two types in our studies.

§Handily applied by Winthrop-Stearns Incorporated, Boston.

During administration of the various aerosols used in this study, patients were instructed to exhale forcibly, then to make a maximum inhalation and finally to hold their breath for a few seconds before exhaling. Vital-capacity measurements were made in the usual manner, and tracings of the expiratory curves were made on a moving drum. Care was taken to ensure maximum effort on the part of the patient. Maximum ventilatory volume was determined by the method of Hermannsen, which has been discussed in detail by Courmand, Richards and Darling.⁸ A 9-liter Benedict-Roth type of metabolism apparatus was used, equipped with special low-resistance valves and with the container for soda lime removed. Computation of results was simplified by the addition to the machine of a recording ventilometer that measured inspiratory volume only.⁹ A maximum ventilatory effort was made for fifteen seconds with the patient choosing his own rate and depth of respirations. Normal values for this method are approximately 150 liters per minute for male and 100 liters per minute for female subjects.

RESULTS

Clinical Use of Isuprel

Thirty asthmatic patients were supplied with isuprel in a concentration of 0.5 per cent to be administered with a hand nebulizer at home. Ten of the 30 patients using the drug at home obtained excellent relief, 14 obtained good relief, 3 obtained fair relief, and 3 obtained practically no relief.

Ten of these 14 patients classified as having received good relief with isuprel stated that this was true only when the attacks of asthma were not severe. While under our observation and using isuprel at home, 7 of these patients developed severe asthma and required hospitalization. In this group 3 other patients, although they were not hospitalized, developed severe asthma with no benefit from isuprel and had to be treated by other measures. We could not determine why these changes occurred, but the severity of the asthma may have been the determining factor.

In addition to the 7 patients who had been using isuprel at home before hospitalization, there were 5 patients with severe asthma who received isuprel for the first time in the hospital. Of these 12 patients, 10 required, in addition to isuprel, intravenous injections of aminophylline, repeated doses of sedatives including demerol, infusions of glucose and saline solution, epinephrine and in some cases oxygen with or without helium.

The patients were not encouraged to continue using isuprel when repeated administration gave only very brief and incomplete relief. We are aware that much more intensive and prolonged administration of isuprel aerosol has been reported to be successful under these circumstances. When continued administration failed to produce subjective

or objective improvement in the asthma of our patients, we abandoned this method of treatment and relied upon the procedures mentioned above. Patients in whom isuprel aerosol had become ineffective in relieving the more severe attacks of asthma frequently found that relief with isuprel was obtained from milder attacks occurring subsequently.

Two patients with severe asthma died unexpectedly. The cause of death appeared to be asthma. We were unable to determine what part, if any, isuprel played in these cases. They are presented in detail below.

CASE REPORTS

CASE 1 A 22-year-old married woman, 6 months pregnant, had been admitted to the Massachusetts Memorial Hospitals five times between March and July, 1947, because of severe bronchial asthma. Since early childhood she had suffered with hay fever in the summer and autumn. At the age of 12, during the ragweed season, she had her first attack of asthma, after which she had asthma perennially, with aggravation of symptoms during the pollinating seasons. On several occasions skin tests had shown positive reactions to cat hair, ragweed, birch, oak, grasses, beef, lobster and walnuts. Over the course of years she had used ephedrine, epinephrine, aminophylline, potassium iodide and barbiturates. She had also received injections of pollen extracts.

Early in 1947, when she was 2 months pregnant, she was seen because of a severe attack of asthma and given isuprel for the first time, to be used by inhalation. This preparation was very satisfactory, and relief lasted from hours to days. Weeks later, however, as the attacks of asthma became more continuous and severe, isuprel became less effective, producing relief lasting only minutes. The patient also failed to respond to repeated large doses of epinephrine and responded only to aminophylline given intravenously. Finally, relief obtained by intravenous injection of aminophylline was incomplete and transitory, and she was hospitalized on June 9, 1947.

Physical examination was not remarkable, except for moderate respiratory distress with a nonproductive cough, wheezes throughout both lung fields and a palpable uterus at the level of the umbilicus.

The blood Hinton reaction was negative, and there was no anemia. Examination of the blood revealed a white cell count of 12,700, with 9 per cent eosinophils.

The asthma was controlled with intravenous injections of aminophylline, epinephrine administered subcutaneously, isuprel by inhalation and barbiturates at bedtime. The patient was discharged on July 3. Subsequently, she continued to have mild asthma, for which she used isuprel repeatedly.

The patient was last seen on the evening of July 9, when she appeared well. Shortly after midnight, because of asthma, she gave herself four subcutaneous injections of epinephrine, and during the following morning and afternoon additional injections of epinephrine were taken, the exact number of which is unknown. For sedation during the night of July 9 she apparently took a total of 0.4 gm (6 gr.) of nembutal, and she may have taken some phenobarbital as well. During this time she continued to use isuprel. Her husband saw her at noon on July 10, and except for a rapid pulse, he did not find cause for alarm. Her mother saw her last about 3.55 p.m., when the patient did not appear in any distress. She went upstairs, and the mother followed about 5 minutes later upon hearing a thud. She found the patient lying on the floor, cyanotic, and breathing with great difficulty. She could not be aroused. Fifteen minutes later she died. Permission for autopsy was not obtained.

CASE 2 A 32-year-old married man was admitted to the Massachusetts Memorial Hospitals on April 19, 1947, complaining of continuous asthma of 2 weeks' duration. His maternal aunt had asthma, and his brother had hay fever. He had had hay fever and bronchial asthma in the fall for 10 years. Treatment with ragweed-pollen extracts had given moderately good results. The asthma had been easily con-

trolled by small doses of ephedrine or epinephrine by injection. Skin tests performed in the fall of 1946 gave positive reactions to many pollens, animal danders and foods. One month prior to admission to the hospital he developed urticaria, which did not respond to epinephrine or benadryl, but finally cleared for no apparent reason.

Two weeks prior to admission he began having severe attacks of asthma with no response to ephedrine, epinephrine or aminophylline. At that time he was given isuprel for inhalation, which gave fairly good relief, sometimes lasting 1 or 2 hours. Gradually, however, this preparation became less and less effective, and the severity of the asthma increased so that finally he had to be admitted to the hospital.

Physical examination revealed a well developed and well nourished man in no acute distress who was wheezing moderately and appeared slightly apprehensive. Wheezes and squeaks were heard throughout both lung fields.

Examination of the blood showed a white-cell count of 7600, with 67 per cent granulocytes and 3 per cent eosinophils. The hematocrit was 48 per cent, and the hemoglobin was 15.7 gm per 100 cc. The urine was normal, except for the slightest possible trace of albumin. X-ray study of the chest revealed slight emphysema.

Because of increasing asthma, the patient received repeated injections of epinephrine, which gave little relief. He also received aminophylline intravenously, to which he responded poorly. Aerosolized isuprel produced slight relief for brief periods. The asthma continued to increase in severity, and the patient became dyspneic and cyanotic.

On the 2nd day in the hospital, late in the afternoon, he complained of marked shortness of breath and he was apprehensive. He received ether in oil by rectum, but because of lack of co-operation less than 30 cc was given. He became comatose and remained so for about 2 hours until suddenly, at about 7:00 p.m., he changed color and the respirations became gasping in nature. Artificial respiration, as well as intracardiac injection of epinephrine, was given to no avail. The patient was pronounced dead at 7:15 p.m.

At post-mortem examination* the heart weighed 355 gm. The endocardium was not remarkable, except for the anterior cusp of the mitral valve, which presented a small rectangular plaque of atheroma. The myocardium showed no evidence of fibrosis or infarction. The coronary arteries were palpable in their proximal few centimeters. There was a moderate degree of atheromatous change in the left and right coronary arteries and in the proximal few centimeters of their descending branches. The maximum amount of stenosis amounted to 50 per cent of the lumen. There was no evidence of coronary thrombosis or coronary occlusion.

The lungs together weighed 1760 gm. They were obviously bulky and voluminous. Their color was light pinkish yellow, with a faint reddish tinge that became more prominent in the lower lobes. The consistence of the lungs was quite rubbery, and they pitted easily on pressure. Moderate pressure produced deep pits, which disappeared slowly. Crepitation was elicited throughout but felt slightly reduced, and the normal spongy texture of the lungs was not felt. The trachea and bronchi contained a moderate amount of whitish, mucoid, very frothy material that did not occlude the lumens. The secondary branches of the major bronchi were completely occluded by bright-yellow, purulent, rather tenacious material, which formed plugs. In the smaller bronchi the plugs became firmer in consistence and assumed a brighter yellow appearance. These were found in perhaps half the bronchi and small branches in all lobes. On cut surface, the color of the parenchyma in all lobes was a light red, with tiny pinhead-sized, darker red mottled patches scattered throughout the lobes. The pulmonary arteries were dissected and found free from thrombus.

The microscopical findings of asthma were striking. The bronchi and bronchioles showed some or all of the following changes. The lumens were partially filled with mucoid exudate, in which were embedded numerous desquamated epithelial cells, lymphocytes, eosinophils and bacteria. The epithelium *in situ* was often reduced to a layer one cell in thickness. Occasional squamous metaplasia was seen. Frequently, the mucosa was infiltrated with neutrophils and eosinophilic polynuclear leukocytes. The basement membranes were thickened and hyalinized and their refractile appearance was striking. The submucosa was densely infiltrated with lymphocytes and large mononuclear leukocytes.

*Performed by Dr. Israel Diamond.

Scattered among these cells were many neutrophils and eosinophilic polynuclear leukocytes. The inflammatory infiltrate extended into the bronchovascular connective tissue and very frequently formed a collar around small blood vessels. The infiltration also extended into the mucous glands in the bronchial walls. The glands were numerous and prominent. In many of the walls, the muscle bundles were thickened and very prominent. The bronchial and bronchiolar lumens were never completely occluded by exudate, although a few bronchioles were seen that were almost occluded by masses of eosinophils. No Curschmann spirals or Charcot-Leyden crystals were found.

The atria and alveoli were markedly distended in most areas. They were empty, except for an occasional large mononuclear anthracotic phagocyte or a few red blood cells. Very occasional patches of atelectasis were found. The alveolar walls were rather diffusely infiltrated with neutrophils and eosinophilic polynuclear leukocytes.

The elastic-tissue stains showed marked fragmentation of elastic fibers in the lamina propria of the bronchi. In a few areas, the elastic tissue had disappeared altogether. The refractile, thickened basement membranes were striking in these preparations. The elastic-fiber proliferation in the intima of some of the arterioles and small arteries, with resulting thickening and narrowing of the lumen, was prominent. Many of the arteries showed reduplication and fragmentation of the elastic laminae.

VITAL CAPACITY IN SPONTANEOUS ASTHMA

Observations were made in 23 subjects with spontaneous asthma. The vital capacity of each subject was determined, and any change after inhalations of isuprel was observed. An increase in vital capacity occurred in every case, and this was usually associated with subjective sensations of relief. As a rule the physical signs of asthma decreased, but in 1 case they increased in spite of a rise in vital capacity and a reduction in the subjective sensation of asthma. In most cases in which small increases occurred, the vital capacity was close to the maximum vital capacity for the patient, as judged by values obtained at periods when no asthma was present. One exception was a patient who was followed during a period in which her symptoms were especially severe. Her maximum vital capacity had been observed earlier to be 2700 cc. On the present occasion her vital capacity was 1500 cc., and after fifteen inhalations of isuprel, it was 1550 cc. The subsequent intravenous injection of aminophylline likewise failed to increase the vital capacity.

COMPARATIVE EFFECTIVENESS OF ISUPREL AND OTHER DRUGS

In a few cases there was opportunity to compare the efficacy of isuprel administered by inhalation with that of epinephrine by inhalation (1:100 solution) and injected subcutaneously (1:1000 solution) and aminophylline given intravenously. We recognized the fact that patients may overestimate the efficacy of a new preparation when it is first used and that some of what follows is perhaps best regarded with this tendency in mind.

One subject received five inhalations of epinephrine 1:100 with an increase in vital capacity from 2150 to 2700 cc. A second series of five inhalations caused a further rise of only 50 cc. The subcutaneous administration of 0.3 cc of epinephrine

(1 1000 solution) caused no further increase in vital capacity in a period of ten minutes. Five inhalations of isuprel (1 per cent) then caused an increase to 3050, and a second series of five inhalations caused a further increase to 3700 cc.

In another subject receiving isuprel for the first time, inhalations of the drug (1 per cent) were given repeatedly over a period of thirty minutes. Marked relief of asthmatic symptoms occurred—the best in many weeks. On the following day the inhalations were repeated, but epinephrine (1 100 solution) was substituted for the isuprel without the

by other routes has been limited and is difficult to evaluate.

RELIEF FROM ATTACKS INDUCED BY INHALED ALLERGENIC EXTRACTS

Observations were made in 9 asthmatic subjects in whom asthma-like attacks were induced by exposure to various aerosolized allergenic extracts by inhalation¹⁰⁻¹². As shown in Table 1, the administration of isuprel caused a rapid return of the vital-capacity readings toward normal. In some cases pyribenzamine or atropine had been given with

†Inhalations of isuprel given over a period of 52 minutes

patient's knowledge. Little relief occurred, and the patient was greatly disappointed. On the third day isuprel was again given, with excellent relief. No vital-capacity studies were made in this patient.

Although most patients who used both epinephrine and isuprel as aerosols stated that the latter was consistently superior, 4 patients stated that epinephrine was as good as isuprel or better, after having had considerable experience with both. The epinephrine preparation used in some cases was a proprietary product containing the drug in a concentration of 2 per cent.

Aminophylline

On numerous occasions patients who were admitted to the hospital for treatment of asthma received both isuprel by inhalation and aminophylline intravenously in doses of 0.25 or 0.48 gm. Although no studies of vital capacity were made, the very definite impression was obtained that aminophylline injected intravenously was superior to isuprel for the treatment of severe asthma. Subjective relief was not only greater but also more prolonged. Experience with aminophylline given

a view to possible protection of the patient from the expected decrease in vital capacity or in an attempt to restore the vital capacity after this had been reduced by exposure to an aerosolized pollen extract. Isuprel was effective in every case but 1, whereas intravenously administered atropine was without influence or had a very slight effect and intravenously administered pyribenzamine rarely influenced the vital capacity under the circumstances of the test. Interpretation of results obtained with tests of this kind is complicated by the tendency of the vital capacity to return toward normal without any treatment. However, inspection of the records obtained in these experiments afforded convincing evidence that inhalation of isuprel was chiefly responsible for the observed rapid increases in vital capacity.

EFFECT OF ISUPREL IN PREVENTING THE REDUCTION IN VITAL CAPACITY AND ASTHMA-LIKE ATTACKS DUE TO PARENTERALLY ADMINISTERED HISTAMINE AND METHACHOLINE

Experiments were carried out in which the effect of isuprel administered parenterally on two occa-

sions and by aerosol on another occasion was observed for evidence of any resulting change in the subjects' susceptibility to injected histamine or methacholine as determined by changes in vital capacity.^{5,6}

In 1 subject the resting vital capacity was 3072 cc and the intravenous injection of 0.02 mg of histamine base produced an asthma-like attack with a reduction of 952 cc in the vital capacity. This type of response occurs in the great majority of asthmatic subjects. In twenty minutes the attack disappeared, and the vital capacity was 3062 cc. A dose of 0.1 mg of isuprel was then given intramuscularly, and within two minutes the pulse was bounding and the rate had increased from 80 to 120 per minute. Marked nervousness, palpitation and faintness were experienced, but these symptoms disappeared within ten minutes, and at this time the vital capacity measured 3103 cc. A second injection of 0.02 mg of histamine base produced no subjective or objective signs or symptoms in the chest, and the vital capacity was not reduced. However, other systemic effects of histamine, such as the gaseous taste in the mouth, flushing and headache, were not prevented by administration of isuprel. A third injection of 0.02 mg of histamine base thirty minutes after isuprel induced slight wheezing in the chest, with a reduction of 920 cc in the vital capacity. It was apparent that isuprel blocked the action of histamine in a manner similar to that of epinephrine,¹³ but its action was short-lived. In this subject 0.1 mg of epinephrine produced no side effects and completely blocked the respiratory effects of 0.02 mg of histamine base after thirty minutes, and some histamine-blocking effect was still demonstrable after sixty minutes.

In another subject, with a resting vital capacity of 4253 cc, the intramuscular injection of 6 mg of methacholine induced an asthma-like attack, with a fall of 1003 cc in the vital capacity. In fifteen minutes the attack had abated and 0.06 mg of isuprel given intramuscularly was followed in a few minutes by palpitation, a rise in pulse rate to 170 per minute and a fall in blood pressure to 70 systolic, 60 diastolic, from the previous level of 120 systolic, 80 diastolic. Eight minutes after the administration of isuprel the vital capacity was 4128 cc. A second intramuscular injection of 6 mg of methacholine produced no subjective or objective changes in the chest, nor was there a significant reduction in vital capacity. However, when the dose of methacholine was repeated thirty minutes after the administration of isuprel, the reaction produced was similar to that before the isuprel had been given. Thus, as in the previous case with histamine, the blocking action of isuprel against methacholine was lost within thirty minutes of the administration of isuprel.

In a third experiment, the subject came to the laboratory with a spontaneous attack of asthma. Four vital-capacity tests averaged 2633 cc. In a period of thirty-eight minutes twenty-four inhalations of isuprel were administered without any side effects, and the vital capacity increased to 3688 cc. At this time 0.02 mg of histamine base given intravenously caused a slight decrease in the vital capacity, and fifteen minutes later 3 mg of methacholine given intramuscularly produced no reduction in vital capacity (Fig 1). In previous studies in this

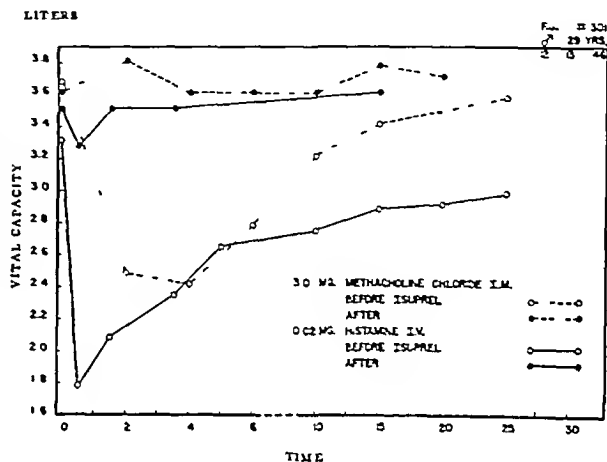

FIGURE 1 Effect of Isuprel aerosol on the Pulmonary Response to Methacholine and Histamine

The curves with the open circles show the effect of injected histamine base and methacholine on the vital capacity. On another occasion, when twenty-four inhalations of isuprel (1:100 solution) had been given for relief of asthma, the tests were repeated, with the results shown by the curves with solid circles. The time is given in minutes elapsed after the administration of histamine and methacholine.

subject the same doses of histamine and methacholine caused pronounced reductions in the vital capacity.

These studies, though few in number, indicate that isuprel furnishes potent protection against the reduction in vital capacity and asthma-like attacks induced by the parenteral administration of histamine and methacholine. Our experience with the intramuscular use of isuprel is obviously limited, but the short-lived protection afforded against histamine and methacholine together, with the degree of side reactions produced by the drug as compared to intramuscular injections of epinephrine, discouraged us from further studies.

SUBLINGUAL ADMINISTRATION OF ISUPREL

Our experience with the sublingual use of isuprel is limited to observations in 13 patients receiving the drug by this route for relief of symptoms at home and in 2 subjects studied in the laboratory.

Patients receiving tablets of isuprel sublingually at home were instructed to take one tablet containing 10 mg at thirty-minute intervals until relief

(1 1000 solution) caused no further increase in vital capacity in a period of ten minutes. Five inhalations of isuprel (1 per cent) then caused an increase to 3050, and a second series of five inhalations caused a further increase to 3700 cc.

In another subject receiving isuprel for the first time, inhalations of the drug (1 per cent) were given repeatedly over a period of thirty minutes. Marked relief of asthmatic symptoms occurred—the best in many weeks. On the following day the inhalations were repeated, but epinephrine (1 100 solution) was substituted for the isuprel without the

Subjective relief was not only greater but also more prolonged. Experience with aminophylline given

a view to possible protection of the patient from the expected decrease in vital capacity or in an attempt to restore the vital capacity after this had been reduced by exposure to an aerosolized pollen extract. Isuprel was effective in every case but 1, whereas intravenously administered atropine was without influence or had a very slight effect and intravenously administered pyribenzamine rarely influenced the vital capacity under the circumstances of the test. Interpretation of results obtained with tests of this kind is complicated by the tendency of the vital capacity to return toward normal without any treatment. However, inspection of the records obtained in these experiments afforded convincing evidence that inhalation of isuprel was chiefly responsible for the observed rapid increases in vital capacity.

EFFECT OF ISUPREL IN PREVENTING THE REDUCTION IN VITAL CAPACITY AND ASTHMA-LIKE ATTACKS DUE TO PARENTERALLY ADMINISTERED HISTAMINE AND METHACHOLINE

Experiments were carried out in which the effect of isuprel administered parenterally on two occa-

THE DIAGNOSIS OF CONGENITAL ANEURYSM OF THE PULMONARY ARTERY*

Report of Two Cases

CHARLES T DOTTER, M D,[†] AND ISRAEL STEINBERG, M D[‡]

NEW YORK CITY

THE literature is filled with accounts of dilations or aneurysms of the pulmonary artery. Notable reviews of the literature have been written by Brenner,¹ Boyd and McGavack² and, recently,

(such as syphilis and mycotic infection), congenital defects causing secondary dilatation (septal patency, patent ductus arteriosus, pulmonic stenosis, transposition of the great vessels and other less common lesions), rheumatic mitral stenosis, a variety of chronic pulmonary diseases that may cause

pulmonary hypertension, thoracic deformities, cardiac failure and possibly trauma.

By our definition, congenital pulmonary-artery aneurysm is an organic, localized or diffuse aneurysmal dilatation of the pulmonary artery that can-

had occurred or until four tablets had been taken in any one day. Of these 13 patients, 3 who were suffering from mild asthma stated that they had obtained excellent relief after taking one or two tablets. Five patients had asthma of moderate severity, and of these, 2 stated that the drug was without effect and the remaining 3 obtained relief of very short duration even with doses as large as 50 mg in two hours. The 5 remaining patients who had severe asthma denied benefit with similar doses.

Two patients with spontaneous asthma were studied in the laboratory. One subject arrived in a mild attack of asthma with an average vital capacity of 2289 cc and a maximal ventilatory volume (M V V) measuring 33.4 liters per minute. The pulse rate was 66 per minute. A 10-mg tablet of isuprel was given sublingually, and in ten minutes the pulse rate was 72 and the M V V 37.6 liters per minute. Again, two 10-mg tablets were given, and ten minutes later the M V V was 48.0 liters per minute, with a pulse rate of 88 per minute. Thus, in a period of forty-eight minutes during which 50 mg of isuprel was administered by the sublingual route no side reactions were experienced, the pulse rate increased from 66 to 88 per minute and the M V V increased 14.1 liters per minute. Subjective relief of the asthma was also experienced. At the end of this period twelve inhalations of isuprel were followed by an increase in M V V to 54.3 liters per minute and the vital capacity was 2874 cc.

In the other subject, spontaneous asthma was present and the M V V measured 45.0 liters and the pulse 120 per minute. At ten-minute intervals a tablet containing 10 mg of isuprel was placed under the tongue until 70 mg had been given. The pulse rate gradually decreased to 104 per minute, and the M V V increased to 65.8 liters per minute. When eight inhalations of isuprel were given, however, there was a rapid increase in M V V to 75.2 liters per minute within ten minutes.

These two experiments suggest that isuprel was not very effective when administered by the sublingual route, except perhaps with large doses. No side reactions were experienced with doses of 50 and 70 mg respectively despite the fact that palpitation and tachycardia were noted after intramuscular doses of the drug as low as 0.1 mg. We recognize the possibility that the physical characteristics of the sublingual tablets and the success patients may have in preventing themselves from swallowing while holding the tablet under the tongue are important factors in the results obtained in studies of this kind.

SIDE EFFECTS

Administration by Aerosol

Only 2 patients in this series of 30 asthmatic subjects experienced symptoms that might reason-

ably be attributed to inhalation of isuprel. In each case nervousness, tachycardia and palpitation were experienced, lasting only a few minutes. In 1 case this followed fifteen inhalations of isuprel (1:100 solution), and in the other, these symptoms followed repeated groups of five to ten inhalations of isuprel (1:200 solution) at short intervals. Both patients used isuprel on other occasions without difficulty.

Sublingual Administration

No side reactions other than a bitter taste were observed in the 15 patients receiving tablets containing 10 mg of isuprel in amounts up to 70 mg within a period of an hour or more. A normal subject receiving one 10-mg tablet sublingually experienced flushing and headache with slight malaise lasting about an hour.

Parenteral Administration

In 5 cases in which isuprel was given subcutaneously or intramuscularly, 2 of which were described above, side reactions were observed. These were tachycardia, palpitation and nervousness in all cases, a fall in blood pressure in 1 case and pallor, nausea and a rise in blood pressure in another. These reactions were not associated with any change in the lung that could not have been readily obtained with isuprel administered by aerosol or with other agents causing fewer or no side effects.

SUMMARY

Isuprel, 1-(3', 4'-dihydroxyphenyl)-2-isopropylaminoethanol, was administered to asthmatic subjects in the outpatient clinic, on the wards and in the laboratory. In most cases the drug was given as an aerosol, but some observations were made in which the drug was given by the sublingual and subcutaneous routes.

The drug given as an aerosol was very effective in relieving mild or moderately severe asthma and appears to be the most effective agent available for self-medication. However, in severe and prolonged attacks of asthma, the drug was far less satisfactory. In certain cases other medications, particularly intravenously administered aminophylline, were required. With recovery, isuprel was again effective in the control of milder attacks. Side effects were uncommon with the doses used in the study.

its greatest superoinferior dimension, and was best seen in the lateral projection. The remainder of the visualization was entirely unremarkable. There was no evidence of septal defect, patent ductus arteriosus, pulmonic stenosis or other congenital cardiac abnormality. The patient continues to be asymptomatic.

CASE 2 A 50-year-old housewife with an otherwise unremarkable past history was thought to have had tuberculous cervical lymphadenitis at the age of 44, evidenced by a painless swelling beneath the left mandible, which disappeared after the aspiration of sterile white fluid containing a moderate number of leukocytes. Culture for tubercle bacilli was negative. At that time x-ray examination of the lung fields was negative, but a prominence in the left hilus was interpreted as tuberculous hilar lymphadenopathy. Over a 6-year period there was no detectable change in the appearance of the left hilar shadow, and angiocardigraphy was then done to rule out the presence of abnormality of the pulmonary artery. At the time of visualization, the patient was asymptomatic.

Physical examination revealed an apparently healthy woman. A few small lymph nodes were felt in the cervical regions, but these were not thought to be significant. Auscultation of the heart revealed the presence of a blowing Grade III systolic murmur in the second and third intercostal spaces to the left of the sternum. The pulmonic second sound was accentuated. There were no other murmurs. The

and both main branches of the pulmonary artery that measured 60 mm in its greatest superoinferior dimension (measured in the lateral projection). The remainder of the contrast study was entirely unremarkable and failed to show evidence of associated congenital anomaly. The patient is

Neo-ropax outlines a dilated main-stem pulmonary artery and its left main branch, which make up the left hilar shadow.

remainder of the physical examination was unremarkable as were laboratory studies, including a complete blood count and Wassermann test. An electrocardiogram showed slight left-axis deviation.

Conventional chest roentgenogram revealed an apparently normal heart and clear lung fields. In the middle portion of the left cardiac border, a prominent, convex shadow that extended out into the left lung field (Fig 4) was seen. On fluoroscopic examination, this was found to have an expansile systolic pulsation. In the lateral projection, a rounded area of density was observed in the mid-hilar region.

Angiocardigraphy in frontal and lateral projections (Fig 5 and 6) outlined an aneurysmal dilatation of the main-stem

at present doing her housekeeping without difficulty and is free of symptoms.

DISCUSSION

An attempt has been made to state the diagnostic criteria for congenital aneurysm of the pulmonary artery. This diagnosis is made by the demonstration of aneurysmal dilatation and by exclusion of the known factors causing such dilatation. Since the assumption is generally accepted that the condition is a true congenital malformation, the term "idiopathic" cannot be applied to it. It is suggested that the condition be termed congenital pulmonary-artery aneurysm, the title implying the presence of an uncomplicated or isolated congenital aneurysm.

The 2 cases reported above fulfill the criteria for this diagnosis. Both patients were asymptomatic, and it is assumed that symptoms would be caused by congenital pulmonary aneurysm only when the aneurysm was of sufficient size to produce compression of adjacent structures. Taussig⁵ reports such a case. Surgical intervention in this condition is contraindicated.

SUMMARY AND CONCLUSIONS

The diagnosis of congenital pulmonary-artery aneurysm may be made in the presence of an

not be accounted for by any of the known causes of pulmonary-artery dilatation. In a given case, the diagnosis cannot be entertained until these factors can be excluded. Many of the cases cited in the literature as aneurysms of the pulmonary artery are associated with such factors, and cannot be

angiocardigraphic study of the normal pulmonary artery has made possible the more accurate evaluation of abnormal findings.⁷ Over a period of eleven years, angiocardigraphic visualizations on more than 650 patients have been accomplished. Of these cases, the clinical and roentgenologic features of 2 allow their classification as congenital pulmonary-artery aneurysms.

CASE REPORTS

CASE 1 A 34-year-old truckman was referred for angiocardigraphy in 1941 because of a prominence at the left hilus seen in a routine preinduction chest roentgenogram. The past and family histories were unremarkable, birth and development had been entirely normal. At the time of examination he was employed as a truckman and experienced no difficulty in doing manual labor. He recalled that he had been refused a job at the age of 22 because a chest film had shown "something around the heart." There was no history of rheumatic fever, and venereal disease was denied.

Physical examination revealed a well developed man whose only significant findings included an accentuated pulmonic second sound, a systolic murmur at the third left

FIGURE 3 Case 1 Angiocardiogram (Left Lateral Projection Three Seconds after the Beginning of Injection)

Superior vena cava, right atrium and superimposed right ventricle, pulmonary artery and left branch are well shown. Note the aneurysmal dilatation of the main stem and left pulmonary artery.

considered to represent congenital conditions. It is difficult to state the dividing line between simple and aneurysmal dilatation of a vessel. Since histologic examination cannot be made during life, and since the vessel wall in congenital aneurysm of the pulmonary artery would probably resemble the normal structure histologically, size remains the most effective criterion. For practical purposes, we refer to a major diffuse dilatation of an artery as aneurysmal. If the dilatation is sharply localized, it is referred to as an aneurysm.

Simple isolated aneurysmal dilatation of the pulmonary artery has been called "idiopathic."^{4, 5} Actually, it is no more idiopathic than a septal defect in that both conditions are true congenital malformations. Angiocardiography has made it possible to delineate pulmonary-artery lesions accurately and to exclude many of the more frequently encountered causes of dilatation.⁶ An

Note the prominent left hilar shadow, which was erroneously interpreted as enlarged hilar lymph nodes.

interspace and in the pulmonic area, and a basal diastolic murmur. The blood pressure was 120/80. Laboratory study, including a complete blood count and Wassermann examination, was negative.

A conventional roentgenogram of the chest (Fig. 1) showed a marked bulge of the pulmonary-artery segment on frontal projection that fluoroscopy disclosed to have an expansile systolic pulsation. On lateral projection, a rounded area of density was seen in the midst of the hilar shadows. The lung fields were clear, and the heart was not enlarged.

Angiocardiography (Fig. 2 and 3) revealed the opacification of an aneurysmal dilatation of the main-stem pulmonary artery and its left main branch. This measured 62 mm in

iodine' and then alcohol. The skin, subcutaneous tissues and periosteum are infiltrated with novocain in a small area just below the iliac crest. The bone-marrow needle is then pushed into the ilium distal to the crest (Fig 1). One usually feels a distinct sense of "give," at which time the stylet is removed, a 10-cc dry syringe is attached and a small amount (0.1 to 0.3 cc) of bone-marrow material is aspirated. Smears are then made directly on specially cleaned glass slides, which are tilted so that most of the blood in the material becomes separated from the flecks of marrow that remain attached to the slide. Then, with the use of the end of another slide, a small portion of the marrow is picked up and smeared gently, with as little pressure as possible, on a third slide. Staining is carried out with a combination of Wright and Giemsa stains.

The *spinous-process puncture* is performed with the patient lying face downward, rather than in the sitting position as recommended by Loge.³ This seems preferable for several reasons. Firstly, the necessary pressure can be more readily employed in the downward than in the horizontal plane. Secondly, the patient lies in a relatively fixed and more comfortable position and cannot be readily moved by the pressure applied. Finally, although the spinous process may be less prominent in the prone than in the sitting and flexed positions, it is easier to isolate and define individually. These reasons are particularly valid in the child. We have utilized a variety of spinous processes and have found that the lower thoracic vertebrae and the lumbar vertebrae are most satisfactory. The patient is prepared with iodine and then alcohol. The spinous process to be utilized is grasped on either side with the thumb and forefinger of the left hand, and the skin, subcutaneous tissue and periosteum are infiltrated with novocain. The bone-marrow needle is then introduced perpendicularly to the process, and after the sense of "give" is felt a syringe is attached and the material withdrawn (Fig 2).

RESULTS

In adults, bone-marrow punctures using multiple sites were performed in 31 patients. Spinous-process punctures alone were done in 25 additional cases. Of the patients with multiple punctures, 3 had sternal, iliac-crest and spinous-process punctures. Comparison of the results obtained with multiple punctures showed surprisingly similar findings, both in the general appearance of the marrow on microscopical study and in the differential counts. Occasionally, marrow was obtained from one site, when another yielded a dry tap. In 3 of our adult cases, multiple punctures revealed hypoplastic or aplastic marrow in three different areas. In 2 of these cases the finding was verified by trephine biopsy. Because of these highly comparable results in different areas, we now utilize

the various sites interchangeably when multiple punctures are performed.

Spinous-process punctures were performed in 25 infants and children ranging from two months to twelve years of age. In 5 children two punctures were done. The iliac-crest puncture was performed in 8. Ten patients had both sternal and spinous-process punctures, 2 patients had sternal, spinous-process and iliac-crest punctures, 2 had iliac-crest and spinous-process punctures, and 1 had a tibial puncture in addition to punctures of the sternum and of a spinous process.

Of the 13 patients who had punctures at multiple sites, comparable results were obtained in 10

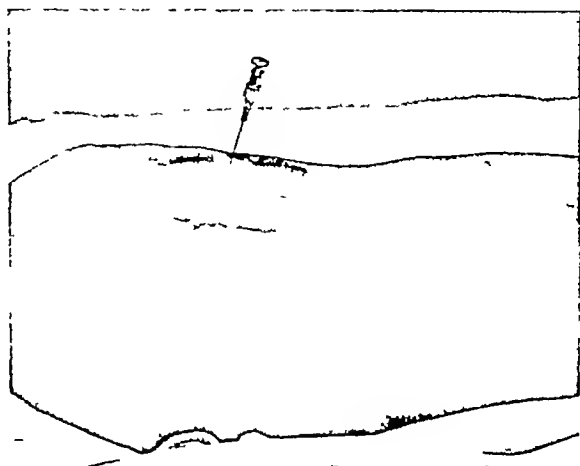

FIGURE 2 Spinous-Process Puncture of an Upper Lumbar Vertebra in an Eight-Year-Old Child, Showing the Position of the Needle (Gauge 18) at the End of the Puncture

In the other 3 cases a diagnosis was made only when multiple punctures were performed. These cases are presented briefly, as follows:

R. C., an 11-year-old child, had possible aleukemic leukemia. Sternal puncture yielded a dry tap. Spinous-process puncture produced a small amount of very thick marrow showing an almost pure culture of lymphoblasts. Apparently, the marrow cavity was packed with very thick marrow, which resisted aspiration. It is possible that a second sternal puncture would have revealed similar findings, but the patient was spared this second puncture of an already sensitive sternum by performance of aspiration at an alternate site.

R. H., a 2-month-old infant, had thrombocytopenic purpura. Tibial puncture yielded no marrow, and two sternal punctures produced very dilute material, suggesting a hypoplastic marrow as the cause of the purpura. A spinous-process puncture revealed an essentially normal marrow, and the infant subsequently made an uneventful recovery. The final conclusion was that the purpura had been of infectious origin.

D. M., who was 3 years and 4 months old, was studied for possible leukemia, aleukemic variety. A sternal puncture and two spinous-process punctures revealed no marrow material. Puncture of the right iliac crest produced material that showed marked infiltration with early lymphoid cells,

aneurysm or aneurysmal dilatation of the pulmonary artery that cannot be accounted for by associated congenital or acquired factors capable of causing pulmonary-artery dilatation

Pressure studies by cardiac catheterization should be carried out whenever possible. The presence of an abnormally high pulmonary-artery pressure must be considered evidence against a congenital pulmonary-artery aneurysm. These studies will be conducted in Case 2.

Angiocardiography adequately demonstrates the nature of the dilatation and aids in excluding other causes of such dilatation.

It is suggested that the term "idiopathic" is misleading and should not be applied to a condition of congenital origin.

Two cases fulfilling these diagnostic criteria are presented

MULTIPLE SITES FOR BONE-MARROW PUNCTURE, WITH PARTICULAR REFERENCE TO CHILDREN*

JACK J. RHEINGOLD, M.D.,† LOUIS WEISFUSE, M.D.,‡ AND WILLIAM DAMESHEK, M.D.§

BOSTON

EXAMINATION of the bone marrow in hematologic disorders by means of puncture aspiration has become in this laboratory and in many

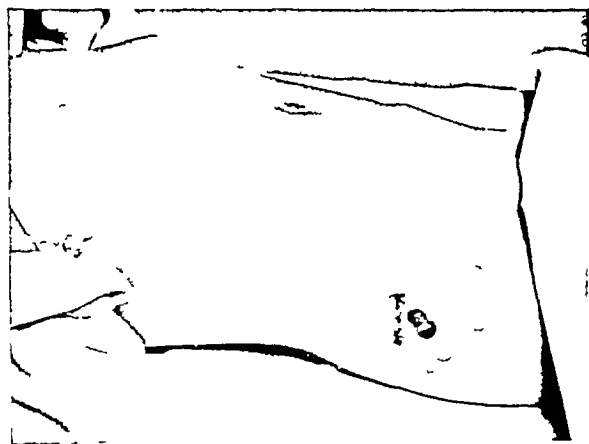

FIGURE 1 Iliac-Crest Puncture, Showing the Position of the Needle (Gauge 16) at the Termination of the Puncture

others a routine study that is often invaluable in diagnosis. Although the sternum is the usual site of such puncture, several investigators have suggested other areas. Thus Van den Berghe and

Blitstein¹ and Rubenstein² have stressed the value of the iliac-crest puncture, and more recently Loge³ and Huss, Gilbert and Liebow⁴ have advocated the spinous process as a site for obtaining a specimen of the bone marrow. Since alternative sites are often desirable we have investigated their value during the past year. Our observations in adults confirm those of the above investigators that essentially similar material is obtained from the various sites taken simultaneously. More recently we have applied the same technique in infants and children and have found that iliac-crest and vertebral punctures are especially valuable in these groups. In infants particularly, the sternal-marrow cavity is quite shallow, and the possibility of perforation into the mediastinum, although remote, is always present. Puncture of the tibial marrow in older children is often unsatisfactory. Furthermore, spinous-process puncture is often preferable for psychic reasons, since the child cannot see the activities associated with the procedure and consequently becomes less alarmed.

METHOD

The same type of stiletted needle is used for the iliac-crest and spinous-process punctures as previously used for the sternal approach.[¶] The needle has a total length of 6.7 cm. and a shaft of 3.3 cm. For *spinous-process puncture* particularly in infants, a No. 1 gauge needle of the above dimensions is preferable. In infants and in young children, light anesthesia as obtained with a few whiffs of ethyl chloride is often useful.

The *iliac crest puncture* is performed after the area about the iliac crest has been prepared with

MEDICAL PROBLEMS OF OLD AGE*

ROBERT T. MONROE, M D J

BOSTON

EIGHT years ago, a geriatric clinic was established in the Out-Door Department of the Peter Bent Brigham Hospital in Boston. Its purpose was to study old people from a fresh point of view in an academic atmosphere. It sought to define the medical problems imposed by age. Are diseases in old people different from the same diseases in younger ones? Are diagnostic problems altered by age? Can useful therapeutic measures and programs be devised? In short, is there a place for geriatrics as a distinct discipline in the medical arts and sciences? This paper is the first report of progress from the clinic.

The location of the clinic excluded attendance by old people of independent means, those too feeble to come, and those in almshouses and private homes for the aged. But there was opportunity to study a few of the first group in private practice and to get information on the rest by association with the Committee on the Care of the Aged of the Boston Council of Social Agencies. Patients who came, though of every kind and condition, proved to be most co-operative and willing to do their part in the explorations. The project has not grown in size, partly because it was curtailed during the war and partly because it has received no financial support except for a few small, unsolicited contributions in the last year. It is still limited to one worker. However, sufficient experience has been gained to show that geriatrics can develop into a real medical specialty and that it is most likely to be developed in clinics where the necessary skills and tools can be fashioned for use by physicians, social workers, nurses, physiotherapists and all who deal with aged persons.

Old age is peculiarly the field of chronic disease. Disabilities and deficits incurred earlier in life are brought along into old age, and new ones appear. Persistent and recurrent diseases, such as peptic ulcer, gallstones, hernia and arthritis, are found in greatest frequency in old age. High blood pressure is observed in the majority of men and women over sixty, and heart disease in some form and degree disables or kills more than 50 per cent of them. Malignant lesions reach their greatest incidence in the aged. These conditions will continue to prevail no matter how much progress is made in particular areas or how long the average span of life

is extended. This accumulation of troubles and our inevitable defeat account for the unhappy view of the last third of life that has always been held by society at large, and for the sense of futility in attempting to cope with its complex situations that most physicians feel. To say, "at your age, what can you expect," absolves the physician from further effort and lets the aged patient conclude that it is all up to him.

The geriatrician holds, however, that this is not sound reasoning. These disabilities come slowly and in varying degrees, so that there is an opportunity for the patient to adjust himself to them, satisfactorily in most cases. It is also clear that even now physicians have enough skill to care for chronic diseases and cardiovascular limitations sufficiently effectively to permit life to be lived at reasonably tolerable levels. Neuropsychiatric disasters are not so unresponsive to treatment as they appear to be. Life ends for many old people as naturally as it began, with little distress, in the midst of full, forward-looking participation in society, with no period of custodial care or sitting on the side-line benches. The geriatrician believes that this happy ending can be achieved by many more.

DETECTION OF DISEASE

The detection of disease in old people is not hard. A thorough search is likely to be only too rewarding. Recognition of the factors that are really producing symptoms, however, many require much insight and geriatric experience. For example, a spinster who for fifty years had made her way as a milliner in a down-town store went to a hospital to seek relief from headaches. Her glasses seemed to be correct. She was found to have high blood pressure. Sclerotic arteries were seen in x-ray films of the skull. She was referred to the neurologic clinic, where the blood pressure, the sclerosis, the headaches and the worries added up to a diagnosis of cerebral arteriosclerosis. She was advised to give up her work, to stop worrying and to sleep on several pillows so that her head would not become congested. She became much worse and had to accept charity. She was referred to the geriatric clinic by her minister. There her headaches were considered to arise from spasm of the erector spinae and trapezius muscles produced by worry and the position of stretch on pillows, and the attacks of vertigo appeared to come from an active carotid sinus reflex. She was advised to sleep without any pillow and to dance, to limber up the neck and to lessen external tension upon the carotid arteries.

and the diagnosis of acute lymphatic leukemia was made. Here again, the dry taps were probably the result of a very thickly packed marrow, which resisted aspiration.

Two cases in this series demonstrate the value of using multiple sites for confirmation of the results obtained from a single puncture. In these patients, aged thirteen and three years and nine months, the differential diagnosis lay between aleukemic leukemia and hypoplastic anemia to explain the pancytopenia. In each case the bone marrow obtained from three sites—the sternum, the iliac crest and the spinous process—showed definite hypoplasia and no leukemic infiltration. In 1 patient further confirmation was obtained by trephine biopsy, which showed a hypoplastic marrow.

DISCUSSION

There are definite advantages inherent in multiple sites for puncture. In such diseases as pernicious anemia, idiopathic thrombocytopenic purpura, multiple myeloma and leukemia, it is often desirable to obtain multiple punctures mainly for the purpose of following the course of the disease or the effects of therapy. When several punctures are performed, not only is the use of multiple sites more readily accepted by the patient but also, with the spinous-process approach, a group of possible sites for successive puncture is available. In one of our patients with pernicious anemia of pregnancy treated with folic acid, five successive spinous-process punctures were made at the seventh, eighth, ninth, tenth and twelfth vertebrae, respectively. The patient reported very little discomfort, and an excellent opportunity was afforded to follow the changes in the marrow after therapy.

In patients in whom the diagnosis is in question and particularly when hypocellular marrow preparations are obtained, the use of multiple sites offers a means of confirmation of marrow diagnosis. A hypocellular marrow preparation obtained by sternal aspiration may leave one in doubt whether this represents a hypoplastic anemia or an inadequate sampling. The finding of hypocellular preparations

in all three sites is a very definite indication that hypoplasia or fibrosis is actually present.

The use of alternate sites may provide information that is lacking if only the sternal marrow is examined. Just as biopsy of a lymph node or of the liver or spleen may throw additional light on a diagnostic problem, so, on occasion, spinous-process and iliac-crest punctures provide data that would otherwise be lacking. For example, in a recent case, the sternal and spinous-process punctures yielded normal marrow, but iliac-crest aspiration showed a well defined infiltration with lymphosarcoma cells, thus establishing the diagnosis.

Additional uses of alternate sites often occur, as when a sensitive patient refuses to have a second sternal puncture, when irradiation of the mediastinum has so affected the sternal marrow that interpretation of the findings of the sternal aspiration may be difficult or open to question, when the sternum is unusually tender to pressure (this occurs in a number of hematologic disorders) and, in certain cases of metastatic disorders, when localized bone pain or tenderness is present. By puncture of the bone in the region of the most marked tenderness, the possibility of finding carcinomatous cells is considerably enhanced.

SUMMARY

In this laboratory, in which examination of the bone marrow is believed to be an integral part of hematologic study, the use of alternative sites for bone-marrow puncture has been found to be of definite value. In children, the spinous process and iliac crest are often the preferred site for puncture.

A series of cases is briefly presented to demonstrate the use and value of punctures at multiple sites.

gestion was this poor, lonely, dependent woman's only claim to importance. She had no excuse for leaving her tenement except to go to church, to the store and to the hospital, where all the specialists were so interested in her. In subsequent visits her habits of living were reviewed, and a girlhood interest in Austrian cross-stitching was revived. At Christmas she exhibited samples of her art in the local saloon, which was the only place in the neighborhood with lighted windows. She continued to need welfare assistance, but no longer complained of gas or burning.

A generalization that time has strengthened was made early in the geriatric clinic: malnutrition and physical and mental unfitness are present in some degree in almost every person over sixty years of age. Malnutrition sets in with lack of a proper diet, as often from wrong ideas about food as from inability to get it. It can come from poor dentures or none. It can result from anorexia due to sorrow or loneliness or loss of drive. It can be intensified by disease, especially diseases with fever, blood loss or cachexia. There is often the hint that the aged organism needs more of certain food factors, such as vitamin B and vitamin C, than have been considered normal amounts for adults, whether from lack of absorption or lack of utilization. Components of the vitamin B complex now constitute the first thought in the clinic for old people with cramps in the legs at night or with unexplained depressions. The war made us conscious of the extra need for protein in cachexia, in hepatitis and in demineralization of bone. Fortunately, an adequate diet is available to all old people in this country—even to those receiving public or private assistance. It is very difficult to get those to take it who cannot change their habits or make substitutions or find value in being well. But the results are worth all the required patience and humor and ingenuity and preaching.

EFFECT OF DRUGS

A great deal of careful observation must be done before it is known whether and to what degree age alters the dosage and actions of drugs. There is an impression that the saturation and maintenance doses of digitalis, for example, are smaller in old persons than in the young or middle-aged. A high concentration of sulfadiazine in the blood is reached rather quickly on small doses, probably because renal filtration is not as efficient in old age. When morphine is administered one should remember the sensitiveness of the respiratory center. Sedatives should be given with much caution, for bromides tend to produce psychotic states and the barbiturates appear to leave the body slowly. The custom of giving small daily doses of phenobarbital to control nervousness and small nightly doses of some other barbiturate to promote sleep is condemned. By their depressive action the drugs in-

crease the fear of loss of mental competence, and by their accumulative tendency they soon fail to produce a satisfactory period of unconsciousness. These objections do not appear to apply to the salicylates or alcohol.

GENERAL THERAPY

The tools that the geriatrician needs are community projects of many kinds. Old-age clubs where lonely, idle persons can go daily for association, for games, for reading, for dances and for developing hobbies are needed. Several are now in existence in Boston. They are not very expensive, but they demand good leadership to control the cantankerous and to bring out the leaners. The natural places for the many more that are needed are the public schools, which are close to old people in every neighborhood, which are for the most part idle in late afternoons and evenings, and which could become truly community centers. Vacation projects are helpful, for elderly persons need the revivifying effects of a change of scene fully as much as young ones, whether or not they are working. Old people on charity seldom get a chance to leave their meager quarters. Most of those who are independently situated live on too narrow a budget to permit a reasonable stay at an attractive place. The management of a farm here, a boardinghouse by the sea there and a camp by a lake somewhere else would be expensive, even if fees were levied according to means. But the benefits derived would be good therapy. And, since most old people would remain at home, there should be summer day-camp club projects in the city, preferably on a portion of public playgrounds, and under supervision to stimulate participation. An employment service, to define and produce paying situations that are suitable for old people and not unfair to young employees, is needed. There should be experiments in boardinghouses, supervised apartments with part-time housekeeping service, simple nursing homes and the activation of homes for the aged to become homes in the full sense of the word and not merely places for custodial care. Best and most expensive of all is an old-age center where all these activities could be housed, directed and promoted, where there could be a gymnasium and swimming pool for rehabilitation, where there could be varied experiments with re-education toward hobbies or jobs or community service, where there could be a psychologic counseling service to determine the aptitudes and mental maturity level as objectively as possible, and where rich and poor could go to find ways to make their last years mean something.

CONCLUSION

The point of view of the geriatric clinic can be summarized thus. There are two groups of old people. There are the very old, those with such

It took several weeks for her to gather courage to carry out the treatment. When she did, her symptoms cleared up. It took much longer for her to get confidence enough to go back to work. Here one can say that the hypertension and arteriosclerosis were anatomic but not clinical facts.

Much that passes for senility turns out to be merely physical unfitness. This is true of much feebleness, frailty, unsteadiness on the feet, awkwardness, undue fatigue, shortness of breath and slow motion. Very few people carry the ideal of a vigorous state of health long after they have left school and its periods of compulsory exercise behind. They exercise as their jobs require or as their vacations or hobbies lead them. When they retire or are retired, inertia seizes them. As a general rule, men in their working years are more fond of keeping physically fit than women are, but after retirement women maintain themselves better because they adjust themselves more naturally to home life than men do. There is no gainsaying the common knowledge that after sixty there are losses in speed and in endurance. But the experience of the geriatric clinic is clear that much can be accomplished, mentally as well as physically, by simple games (bowling, shuffle board and ring toss) and by dancing to restore the sense of timing and coordination. The clinic patients have responded well when the only available outlet was their own ingenuity and the radio. It is also clear that regular exercise and play have beneficial effects on patients with high blood pressure, hypertensive heart disease, arthritis, emphysema, paralysis agitans and hemiplegia. Here is a field of rehabilitation as exciting and as rewarding as that with war casualties. A great deal is packed into the phrase of Juvenal *mens sana in corpore sano*.

Much that appears to be mental deterioration in old age is not so at all. Perhaps not more than 10 to 15 per cent of old people show organic, irreversible losses of mental functions. Very few people study after their school days, except as their livelihood compels them. Their reading may be limited to newspaper headlines and magazines. When they lose their jobs, they often find themselves too rusty to activate unused aptitudes or restore neglected hobbies and studies, and they drift along idly on daydreams. Or an accident, loss of sight or hearing or locomotion, loss of family or friends or fortune, loss of accustomed reasons for living finds them so concentrated on their misfortunes that they have no attention to give to things that go on around them. Therefore, these things are not remembered, and, since loss of memory is a sign of old age, they are thrust deeper in depression by being made aware of that fact. They depend upon others to remember things or to do tasks that the limitations of old age prohibit, and dependency paralyzes their intellectual output still more. Certain diseases produce flagrant states of psychoses, which clear up when

they are cured or controlled — for example, severe anemia, high fever, severe heart failure and obstructive situations in the urinary tract. The geriatrician is conscious of how important it is for the mental health of his patient that he treat vigorously every interfering ailment and find ways of restoring confident living.

It is appropriate that the old person's chief complaint may have little to do with what really concerns him. Even if it does, there are other complaints and many matters that he needs to talk over with someone. He has outlived the parents to whom he turned in time of trouble. His friends are gone, and now, still the same human being, in the dark about how to pursue his course, or how to find a course to pursue, he must bring himself to turn for advice to younger people, it is equally difficult for younger people to give him an attentive ear — for the pupil to turn teacher. Who is in a better position to give friendly, neutral, skillful, understanding advice than the medical adviser? Here is a tremendous extension of medical responsibility far beyond what can be taught in school or laboratory. But the old-fashioned general practitioner fulfilled this responsibility. It is a burden that practitioners today must recognize and assume if they are to deal adequately with the needs of old people. It takes an endless amount of time, much insight and ingenuity, tolerance and patience. The reward is in making the last third of life worth while to many persons.

A typical problem in geriatrics is illustrated by the first patient referred to the clinic. She was a sixty-eight-year-old Austrian widow who complained of belching of gas and epigastric burning. She had been studied by every medical house officer in the Peter Bent Brigham Hospital in the course of the previous five years, four gastrointestinal series, two barium enemas and two x-ray examinations of the gall bladder were negative, all therapeutic reassurance and diets and medications were of no avail. She sat across a narrow table from the examiner and for an hour and a half described and illustrated her symptoms. Her appearance was not prepossessing, for the motion of her false teeth did not synchronize with the tremor of her head. The examiner, determined not to abandon geriatrics at the first shot, asked questions from time to time — who she was, where she came from, how she lived. Finally, she began to answer them, and for ten minutes she gave a detailed story of her origin and emigration to America, where she stayed first, where she worked, how she met and married her husband, how he had died and how she had subsequently lived. She was asked to return in a week to discuss ways of spending her welfare allowance to better advantage, and it was then pointed out to her that she had not belched in the last ten minutes. "Oh," she said, "that doesn't bother me." And then it dawned upon the examiner that her nervous indi-

gestion was this poor, lonely, dependent woman's only claim to importance. She had no excuse for leaving her tenement except to go to church to the store and to the hospital, where all the specialists were so interested in her. In subsequent visits her habits of living were reviewed, and a girlhood interest in Austrian cross-stitching was revived. At Christmas she exhibited samples of her art in the local saloon, which was the only place in the neighborhood with lighted windows. She continued to need welfare assistance, but no longer complained of gas or burning.

A generalization that time has strengthened was made early in the geriatric clinic: malnutrition and physical and mental unfitness are present in some degree in almost every person over sixty years of age. Malnutrition sets in with lack of a proper diet, as often from wrong ideas about food as from inability to get it. It can come from poor dentures or none. It can result from anorexia due to sorrow or loneliness or loss of drive. It can be intensified by disease, especially diseases with fever, blood loss or cachexia. There is often the hint that the aged organism needs more of certain food factors, such as vitamin B and vitamin C, than have been considered normal amounts for adults, whether from lack of absorption or lack of utilization. Components of the vitamin B complex now constitute the first thought in the clinic for old people with cramps in the legs at night or with unexplained depressions. The war made us conscious of the extra need for protein in cachexia, in hepatitis and in demineralization of bone. Fortunately, an adequate diet is available to all old people in this country—even to those receiving public or private assistance. It is very difficult to get those to take it who cannot change their habits or make substitutions or find value in being well. But the results are worth all the required patience and humor and ingenuity and preaching.

EFFECT OF DRUGS

A great deal of careful observation must be done before it is known whether and to what degree age alters the dosage and actions of drugs. There is an impression that the saturation and maintenance doses of digitalis, for example, are smaller in old persons than in the young or middle-aged. A high concentration of sulfadiazine in the blood is reached rather quickly on small doses, probably because renal filtration is not as efficient in old age. The custom of giving small daily doses of phenobarbital to control nervousness and small nightly doses of some other barbiturate to promote sleep is condemned. By their depressive action the drugs in-

crease the fear of loss of mental competence, and by their accumulative tendency they soon fail to produce a satisfactory period of unconsciousness. These objections do not appear to apply to the salicylates or alcohol.

GENERAL THERAPY

The tools that the geriatrician needs are community projects of many kinds. Old-age clubs where lonely, idle persons can go daily for association, for games, for reading, for dances and for developing hobbies are needed. Several are now in existence in Boston. They are not very expensive, but they demand good leadership to control the cantankerous and to bring out the leaners. The natural places for the many more that are needed are the public schools, which are close to old people in every neighborhood, which are for the most part idle in late afternoons and evenings, and which could become truly community centers. Vacation projects are helpful, for elderly persons need the revivifying effects of a change of scene fully as much as young ones, whether or not they are working. Old people on charity seldom get a chance to leave their meager quarters. Most of those who are independently situated live on too narrow a budget to permit a reasonable stay at an attractive place. The management of a farm here, a boardinghouse by the sea there and a camp by a lake somewhere else would be expensive, even if fees were levied according to means. But the benefits derived would be good therapy. And, since most old people would remain at home, there should be summer day-camp club projects in the city, preferably on a portion of public playgrounds, and under supervision to stimulate participation. An employment service, to define and produce paying situations that are suitable for old people and not unfair to young employees, is needed. There should be experiments in boardinghouses, supervised apartments with part-time housekeeping service, simple nursing homes and the activation of homes for the aged to become homes in the full sense of the word and not merely places for custodial care. Best and most expensive of all is an old-age center where all these activities could be housed, directed and promoted, where there could be a gymnasium and swimming pool for rehabilitation, where there could be varied experiments with re-education toward hobbies or jobs or community service, where there could be a psychological counseling service to determine the aptitudes and mental maturity level as objectively as possible, and where rich and poor could go to find ways to make their last years mean something.

CONCLUSION

The point of view of the geriatric clinic can be summarized thus. There are two groups of old people. There are the very old, those with such

limitations of body, mind and pocketbook that they need custodial care, these are the ones on whom most attention has been centered and the ones we have in mind when old age is thought of with dismay. But there are also young old people, most of them independent or at work. We must direct our efforts at them. If we do, if we discover means of keeping them at work, if we find ways for them to rehabilitate themselves physically and intellec-

tually, if they are given adequate care in sickness and convalescence, and if they have normal opportunities for play, vacations, social association and community participation and for living, many of them will retain their independence, and the break to custodial care will be of short duration or will not come at all.

CLINICAL NOTE

CONSERVATIVE TREATMENT IN PLACENTA ACCRETA

REPORT OF A CASE IN TWIN PREGNANCY

SAMUEL P. NORMAN, M.D.*

MALDEN, MASSACHUSETTS

THE abnormal adherence of all or part of the placenta to the uterine wall, so-called placenta accreta, is a complication in obstetric practice that calls for accurate, rapid diagnosis, and perhaps emergency treatment. It is not a common finding, Irving and Hertig¹ record the incidence at the Boston Lying-in Hospital to be 1 in 1956 deliveries. The survey by Phaneuf² reveals a frequency of 1 placenta accreta in 14,622 deliveries. There is only one previous report of placenta accreta occurring in twin pregnancies.³

The dangers of hemorrhage and sepsis in adherent placentas have made immediate hysterectomy the accepted treatment. However, conservative therapy may have a definite place, especially when there is complete absence of uterine bleeding. In the following case of placenta accreta in twin pregnancy the patient was treated without surgical intervention.

Mrs. M. P., a 27-year-old primigravida, whose last menstrual period had begun on July 12, 1947, was admitted to the Malden Hospital on March 21, 1948, in premature labor. Pregnancy up to that time had been normal. The patient was Rh+. Under low spinal anesthesia, a living premature female infant was delivered by Scanlon maneuver, after a right mediolateral episiotomy. Immediately after the birth of the infant, a large placenta with membranes and cord was delivered intact. At this time, it was noted that the uterus was still large, and within a few moments, a macerated still-born female fetus was delivered along with an umbilical cord about 30 cm. in length broken off at its distal end. A second placenta and membranes did not present.

The first placenta was examined very carefully, and no place could be found where the second umbilical cord might have been attached. There was no sign of hemorrhage. After 45 minutes, the uterus was entered in an attempt at manual extraction of the second placenta, but no line of cleavage could be felt. A second obstetrician, called in consultation,

was also unable to find a line of cleavage but did remove a few shreds of membrane. There was still no bleeding, and the patient's condition was good despite manipulation. The blood pressure was 120/70, the pulse 84, and the respirations 20. The flow was normal. Since the fundus was hard, firm and well contracted, all operative intervention was discontinued, and the patient was returned to her bed. On the following morning, the placenta had not been expelled. The patient was not bleeding and her blood pressure, pulse and temperature were normal. Penicillin was administered in a dosage of 100,000 units every 3 hours for 4 days. It was decided to observe her progress for at least 36 hours before considering surgery since there was no apparent indication for hysterectomy. At the end of this period, the patient was in excellent condition. The flow was not excessive, and the uterus was contracted and firm. A final decision against removal of the uterus was made. The patient was discharged 10 days after delivery, after an uneventful convalescence. Post-partum examination 6 weeks later revealed a well healed perineum and a normal fundus. She had a normal menstrual period 8 weeks after delivery.

In this case the question of a placenta succenturiata was considered as well as that of accreta, but pathological examination of the placenta revealed no site where the umbilical cord might have been inserted.

Nearly all writers agree that the treatment of placenta accreta is immediate hysterectomy. However, Schumann⁴ cites special indications for conservative treatment and presents a series of 14 cases with no mortality and 2 subsequent pregnancies. His chief indication for conservative treatment is absence of bleeding.

In considering the fate of the placenta that was not expelled, one must hypothesize that since the fetus was stillborn and the first placenta was very large, the second placenta must have been very small and that, because of its small size, it did not have a sufficient blood supply and therefore degenerated. Secondly, this might have been an increta or percreta type of placenta (Kaltreider classification), which had so grown into the uterine musculature that it could not be removed.

This case was similar to those reported by Schumann.

SUMMARY

A case of placenta accreta occurring in a twin pregnancy with one live infant and one macerated fetus is presented. The patient was treated conservatively and made an uneventful recovery.

MEDICAL PROGRESS

CARE OF THE NEWBORN*

STEWART H CLIFFORD, M D †

BOSTON

FOR many years neonatal mortality rates resisted all efforts at reduction. In Massachusetts from 1910 to 1930 the infant mortality occurring from two weeks of age to one year fell over 60 per cent while the neonatal death rate fell but 14 per cent (Fig 1). However, during the past fifteen years there has been a gratifying fall of 32 per cent in neonatal mortality, from a rate of 31 deaths per 1000 live births to a rate of 21. Despite this improvement the first two weeks still remains the most dangerous period in life — 64 per cent of the present infant mortality in the Commonwealth occurs during that interval.

A number of factors have contributed to the recent reduction in neonatal mortality. All people have enjoyed a higher standard of living, with resulting improved nutrition in the child-bearing group and the ability to command better medical care. There have been great advances in the sciences of obstetrics, pediatrics and public health and wide dissemination of this knowledge to the medical profession and general public. The federal Government, through the Children's Bureau, has paid particular attention to the welfare of the newborn, and much of the present success can be traced to these efforts. The district and local health departments have been very active in promoting programs to improve the care of the newborn, with splendid results. Not the least of the factors contributing to the improved status of the newborn has been the rapid shift of the scene of childbirth from the home to the hospital. In Massachusetts during the past year 96 per cent of all births took place in hospitals. While the over-all picture has improved, the shift from the home to the hospital has not been an unmixed blessing but has of itself created new problems, which are considered below.

PRENATAL PROPHYLAXIS

The health and nutrition of the mother from the time of conception on may exert a direct influence on the developing embryo and fetus. The classic animal experiments of Warkany¹⁻³ have demonstrated that maternal diets completely deficient in vitamin A, B or D during the breeding period and the following fourteen days will produce a high incidence of malformation in the young, each vitamin lack producing a different and characteristic type of abnormality. These findings on animals must be applied to the problems of human nutrition with caution since no diet for human beings could be deprived of vitamins to the extent necessary to produce abnormalities in rats. Burke and his associates⁴ analyzed the diets of 216 women observed throughout pregnancy and found in the 36 women on poor diets 8 infants with congenital anomalies whereas but 1 occurred in the group of 31 mothers on good diets.

Infection due to the rubella virus,⁵ occurring early in pregnancy, has been found to cause congenital malformations in the newborn such as congenital cataracts and heart disease, deaf mutism, mongolian idiocy, microcephaly, hydrocephaly and mental retardation. Ingalls⁶ believes that mongolism may be the result of injury to the embryo between the sixth and ninth weeks of life. He contends that agents responsible for this injury may include hemorrhage, threatened abortion, pathologic abnormalities of the uterus and certain acute infections. He suggests that these agents injure the embryo through anoxia, through temporary starvation or through the accumulation of toxic metabolites.

Ingalls states that forty years ago Mall stressed the importance of faulty implantation of a normal ovum in the production of a pathologic embryo and that, at the same time, Stockard concluded that two main mechanisms were involved in ab-

normal development. In one the abnormality was of germinal origin, producing accidents such as albinism, certain legless conditions and polydactyly. In the other, true monsters arose from normal ova developing under abnormal conditions or under unusual circumstances.

A number of studies have been made on the influence of prenatal factors on prematurity. Ebbs, Tisdall and Scott⁷ found the incidence of miscarriages, premature births and stillbirths to be

of prenatal influences. Studies in this new field of prenatal prophylaxis should bring rich rewards both in reducing the incidence of stillbirths, premature births and congenital abnormalities and in improving the health of the newborn infant at birth.

NATAL PROPHYLAXIS

The present methods of safeguarding the baby during delivery represent one of the greatest achieve-

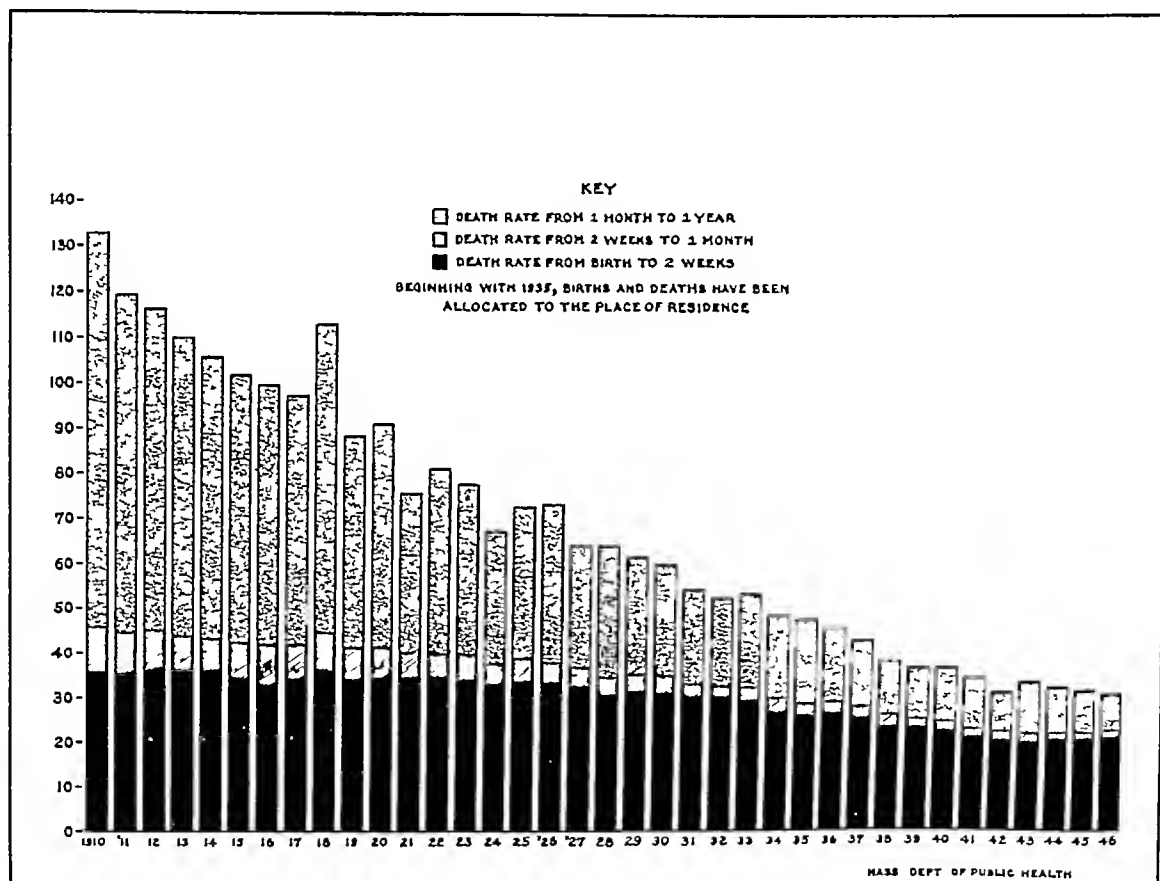

FIGURE 1 Infant Mortality in Massachusetts by Age Groups per 1000 Live Births

greater in a group of women on poor diets. Burke et al⁸ reported that the occurrence of stillborn, premature and functionally immature infants, as well as those with marked congenital defects, was practically limited to a group of mothers whose diet during pregnancy had been inadequate.

Brown, Lyon and Anderson⁹ found the incidence of prematurity significantly increased by maternal illness, severe toxemia, eclampsia, mild bleeding, placenta previa, premature separation of the placenta, acute infections and chronic disorders of pregnancy.

It is thus apparent that many of the problems encountered in the newborn may be the aftermath

of modern obstetrics. The major dangers from which the infant must be protected result from trauma and anoxia.

Serious traumatic injury to the infant during delivery is now practically never seen. One important milestone in the elimination of traumatic injury was the substitution of physiologically sound pressure from above for traction from below. Almost overnight brachial palsies and spinal-cord transections disappeared and gross intracranial hemorrhages became exceedingly rare. Another important step was maternal analgesia that was safe for baby as well as mother. Because of the analgesia the mother was allowed to proceed through labor without inter-

ference, and the incidence of high-forceps and mid-forceps extractions also practically disappeared. The third important milestone in the elimination of traumatic injury was the introduction of x-ray pelvimetry and the following of the progress of doubtful cases by serial x-ray examination. It is possible, but not proved, that the administration of vitamin K to the mother during labor has reduced the incidence of intracranial bleeding.

Protection of the infant from the devastating effects of anoxia is one of the major problems with which obstetricians are confronted today. In this clinic 58 per cent of the deaths among infants, both full term and premature, are the result of anoxia. There are, to be sure, many complications of pregnancy in which serious anoxia is unavoidable and beyond present methods of control. However, some types of anoxia are completely preventable. The use of high concentrations of nitrous oxide or of cyclopropane during labor will inevitably produce severe fetal anoxia. The practice of delaying delivery of the head by direct or indirect pressure to the perineum with or without deep maternal anesthesia is indefensible and extremely dangerous. It is frequently a tragedy that the baby involved in such a procedure survives but with gross neurologic damage.

NEONATAL PROPHYLAXIS

Hospitals have assumed a tremendous responsibility in attempting to provide care for all the newborn infants in the nation. The considerable confusion that surrounds the problem is due to a number of factors: the speed at which the shift from home to hospital took place, the shortage of hospital and nursery beds, the increased birth rate, the demand for care by a private physician and for private and semiprivate rather than ward accommodations, the shortage of nursing personnel, the problem of increasing costs and unbalanced budgets, and the unco-ordinated attempts by the overlapping interested groups of doctors, nurses, administrators and public-health authorities to offer independent solutions for the problem.

The position of the public-health authorities toward the care of the newborn in hospitals is clear. They must represent and protect the interests of the general public by establishing, after consultation with all interested groups, minimum standards and regulations for the hospital care of newborn infants as a basis for the yearly licensing of such obstetric units. They must make sufficiently frequent personal inspections to satisfy themselves that these minimum requirements are being continuously met.

The hospitals themselves should not be content with minimum standards but should strive at all times toward ideal care for their babies. The Committee on Fetus and Newborn of the American Academy of Pediatrics has committees on fetus and

newborn organized in forty-seven states, four Canadian provinces and Hawaii, and each committee is anxious to co-operate with any hospital group in helping to solve its individual nursery problems.

Any hospital seeking to organize and improve its newborn service can obtain valuable assistance from the Manual, *Standards and Recommendations for Hospital Care of Newborn Infants—Full Term and Premature*, prepared by the Committee on Fetus and Newborn of the American Academy of Pediatrics and now in press.

DISEASES OF THE NEWBORN

The major causes of morbidity and mortality in newborn infants, full term and premature, are relatively few—anoxic injuries, traumatic injuries, infections, congenital defects and erythroblastosis. It is of great practical importance that the vast majority of these conditions can be recognized within the first forty-eight hours of life. It would be highly desirable, therefore, if all newborn infants could be closely observed and examined by specially trained nurses and pediatricians, if possible in a special nursery, for the first twenty-four to forty-eight hours of life, before being distributed to their regular nurseries.

By all standards the most important cause of newborn morbidity and mortality is anoxic injury, which alone accounts for nearly 60 per cent of mortality. Anoxia¹⁰ produces progressively congestion, edema, hemorrhage and necrosis in any or every organ and tissue of the body. The combinations of clinical symptoms that may result are almost unlimited. The only treatment that will stop the cycle of anoxic injury is the administration of oxygen. Many newborn infants are immediately placed in an atmosphere of 50 to 60 per cent oxygen as a prophylactic measure even before clinical symptoms have become evident. Undoubtedly, more oxygen than is necessary is used, but it is believed that this procedure has prevented the occurrence or minimized the extent of dangerous complications in an unknown number of infants. All prematurely born infants are routinely placed in an oxygen bed for at least twenty-four hours, and all those with erythroblastosis severe enough to require treatment, and all those with atelectasis are kept in oxygen for four or five days. All babies with a history of fetal distress and all who have required resuscitation are automatically placed in oxygen.

The generalized edema that develops in both full-term and premature infants as the result of anoxia is a very striking finding. It may be a fatal error to start giving fluids too early to such infants in the presence of edema. The added fluid increases the existing edema and may produce serious cerebral and pulmonary complications. It is a fixed policy to give no fluid to premature or full-term infants in the presence of edema. In rare cases

a small premature infant may receive nothing for as long as four or five days. This principle of managing edema was postulated on clinical grounds and has been associated with a further lowering of premature infant mortality to 16 per cent. The work of Smith¹¹ has now given chemical support to this thesis.

Infants with intracranial bleeding,¹² whether due to anoxia or trauma or both, are kept in oxygen, given nothing by mouth for several days and treated by repeated lumbar punctures until the spinal fluid is practically normal.

The birth of erythroblastotic infants may be forecast weeks before term by the appearance of anti-Rh agglutinins in the serum of mothers with a suggestive history and Rh setup. When it is obstetrically advisable these babies are delivered several weeks before maturity. Blood from the infant's umbilical cord is immediately studied for Rh type and the presence of Rh antibodies. If circulating antibodies are demonstrated the infant receives an immediate replacement transfusion with Rh negative blood. Under this routine the mortality from erythroblastosis has fallen from 40 to 10 per cent.¹³ Unfortunately, the incidence of kernicterus has not been reduced by present methods of treatment.

Pediatricians have an increasing obligation to recognize certain congenital defects early in the newborn period since an increasing number can be cured by prompt surgical procedures. Only a few years ago all babies with a tracheoesophageal fistula died—today 8 out of 10 should be completely repaired.¹⁴ Every infant exhibiting an unusual amount of oral mucus immediately after birth should be suspected of having this condition until the contrary is proved. The diagnosis is made by the demonstration of a blind esophageal pouch through the passing of a stiff catheter into the esophagus and the taking of an x-ray film with the catheter in place.

One in every 4 infants with congenital absence of the bile ducts has a condition that may be cured by surgical intervention.¹⁵ It must be remembered that jaundice may be very slight in this condition throughout the newborn period. Every case of even mild jaundice must be considered as a potential congenital obliteration of the bile ducts until proved to the contrary.

Congenital obstruction of the intestine is a relatively common condition in the newborn—including premature infants. Every case of vomiting in the newborn, especially if it begins immediately after birth, must be considered obstruction until disproved. The obstruction may be intrinsic and, if multiple, may be inoperable. It may be due to meconium ileus and require operation or to a meconium plug in the rectum or descending colon and respond dramatically to a simple enema. It may be caused by constriction by short bands of

mesentery associated with malrotation of the cecum or by a volvulus, intussusception, pyloric stenosis or diaphragmatic hernia. A 3-pound premature infant with an obstruction due to an annular pancreas was successfully operated upon on the sixth day of life. The common symptom of obstructions is vomiting, and the diagnosis can frequently be made by a plain x-ray film of the abdomen.

INFECTION

It should never be forgotten that both premature and full-term infants may develop all the types of infection seen in older infants. They are particularly susceptible to infections that may enter through the umbilical vessels. However, at present I am particularly concerned with a relatively new type of infection that has appeared secondary to the concentration of large numbers of babies in common nurseries. Epidemic diarrhea of the newborn has become a public-health problem only during the past fifteen years.

A review of the literature on this condition¹⁶ warrants the conclusion that it is not a pathologic entity but rather a symptom complex that may be caused by a variety of organisms and by at least one and possibly more viruses. The conclusion was reached that many epidemics were caused by glaring errors in nursery technic and by faulty epidemiologic management of the first cases of diarrhea that appeared. It was suggested that simple sound nursery practice could prevent practically every epidemic of diarrhea even in crowded nurseries.

The New York State Public Health Council on January 16, 1948, added a new regulation to its sanitary code designed to control diarrheal diseases of the newborn in nurseries.¹⁷ These regulations were arrived at after consultation with the New York State Medical Society, many individuals and organizations and were written to agree in principle with the recommendations of the Children's Bureau and the Committee on Fetus and Newborn of the American Academy of Pediatrics. The New York Department of Health summarizes the requirements of Regulation 35 as follows: mandatory terminal "sterilization" of formulas in individual feeding bottles with nipple and nipple cap attached, certain principles of isolation, the use of the "suspect" nursery systems for observing infants with suspicious signs of illness, individual care for each infant with his own equipment, adequate space for such care, adequate nursing personnel, smaller groups of infants in each nursery and careful handwashing by physicians and nurses after coming in contact with any infant.

A similar program was proposed, but not made mandatory, by the Massachusetts Department of Public Health at a series of conferences throughout the Commonwealth in June, 1947. Dr. Roy F.

Feemster, director of the Division of Communicable Diseases, has given me permission to report the amazing sequel of these conferences. In the period from June, 1946, to June, 1947, the Department of Public Health was forced to close the newborn nurseries of 9 maternity hospitals because of outbreaks of epidemic diarrhea. All these outbreaks were serious, with fatal cases in each. From June, 1947, to April, 1948, there was not a single epidemic of newborn diarrhea in the Commonwealth. The Department was called in by 11 hospitals with isolated cases of newborn diarrhea, no nursery was closed, and no deaths occurred in any of the reported cases.

CARE OF THE PREMATURE INFANT

Care of the prematurely born infant is the major problem of the neonatal period. Every hospital can anticipate that 5 or 6 per cent of their expected births will be infants weighing 2500 gm (5 pounds and 8 ounces) or less and that from this small group will come 60 per cent of the newborn mortality.

The Children's Bureau¹⁷ has been a leader in efforts to improve the care of premature infants and is ever ready to assist state and local groups in their problems. Since 1935 the Bureau has had the responsibility of administering grants-in-aid to states for maternal and child health under the Social Security Act. The maternal-health and child-health fund available for state grants amounts to \$11,000,000 per year, half of which goes to states in proportion to their number of live births and must be matched dollar for dollar from state funds. To receive its share a state must submit a plan outlining its proposed program and indicating how it will meet certain requirements of the act. Forty-four states have some activity in relation to premature infants financed from maternal-health and child-health funds. At present 7 states have premature centers now in operation, and 6 more states are in the process of starting such centers. Most of the states concentrate on one, two or three good centers to which premature infants are brought by ambulance.

The details of organizing, equipping and operating a nursery for premature infants are beyond the limits of this discussion and may be found in *Care of Premature Infants*, published by the Division of Maternal and Child Hygiene, Illinois Department of Public Health, in the *Recommended Standards for the Care of Premature Infants*, of the Bureau of Child Hygiene, New York City Department of Health, and in the manual mentioned above that is to be published by the Committee on Fetus and Newborn of the American Academy of Pediatrics.

Methods to protect the premature infant from infection deserve some consideration. If it is granted that for practical purposes all premature infants at the moment of birth are free from infection, it

is a striking fact that in some nurseries infection of premature infants, usually accompanied by diarrhea, is virtually unknown, whereas in other nurseries it is a constant major problem. It is my strong conviction from years of experience with the problem that premature infants born in a hospital devoted exclusively to obstetrics, where the medical and nursing staff have no contact with infected general-hospital patients and no contact with other doctors and nurses caring for such patients, are peculiarly free from infection, with or without diarrhea. Premature infants born in the obstetric ward of a general hospital, even when cared for in a separate nursery, are prone to infection and diarrhea. Premature infants transported to a premature nursery setup in connection with a general pediatric hospital are particularly susceptible to infection and diarrhea. In my own experience the incidence of infection and diarrhea has been sharply curtailed—but not eliminated—in a premature nursery operated as part of a general infants' hospital when each premature infant is kept strictly isolated in a Chapple bed.

As a result of the above experience I recommend that premature centers be located in obstetric hospitals, in an independent building widely separated from a general hospital with a completely independent staff, if in connection with a general hospital—as far away from the children's and infants' wards as physically possible and equipped so that each infant can be kept and cared for in its own air-conditioned unit throughout its entire stay.

CULTIVATION OF A NORMAL MOTHER-INFANT RELATION

McLendon¹⁸ has summarized the cultivation of a normal mother-infant relation as presuming breast feeding, observation by the mother of her newborn child's development, partial care of her newborn infant commensurate with her physical ability, the consequent accumulation of knowledge of her infant's behavior characteristics, particularly in connection with hunger, and confidence in her ability to interpret behavior expressions and to handle them properly.

Macneill¹⁹ points out that the *place* of birth has a definite relation to breast feeding. In Detroit the incidence of breast-fed babies varied from 5 to 6 per cent in one hospital to 69 per cent in another. In Philadelphia a survey in two hospitals revealed a ratio of 24.6 per cent to 83.3 per cent. Common experience indicates that such discrepancies between hospitals exist.

Aldrich²⁰ has summarized the advantages of breast milk as a specific food and the advantages of breast feeding as a technic in child care. In connection with breast feeding he points out that teachers and laymen interested in the emotional problem of children, psychologists, psychiatrists and pedi-

atricians interested in growth and development all emphasize that this form of feeding provides a greater feeling of security to the baby. Through nursing at the breast the baby may gain a feeling of physical continuity with his mother, which as he progresses may lead to the feeling of "belongingness" considered by many psychiatrists to be the first step in the normal mother-child relation. The mother herself may benefit physiologically and psychologically through thus demonstrating her real importance to the infant.

The mother must be "sold" on the idea of wanting to nurse her infant—if possible, during the prenatal period. Many obstetricians begin this process of education at the first prenatal visit. Everyone knows how futile it is to try to convince a young mother that she should nurse her baby if her mind has been made up to the contrary. Aldrich²⁰ states that many psychiatrists consider that if a mother actively rejects the idea of nursing, it is probably unwise to urge it.

The obstetric department, psychiatric consultant and nursing school are experimenting with prenatal clinics on the psychologic preparation of the patient for childbirth in which the importance of future breast feeding is not neglected. It is too early to quote results, but the number of infants completely breast fed on discharge has risen to above 50 per cent.

Real help is needed for reducing the number of breast-feeding failures in willing mothers. Macneill¹⁹ gives an excellent consideration of this problem. He considers some cracked nipples to be caused by the infant's efforts to obtain milk from an obstructed channel, the obstruction persisting unless the tension within the breast is lessened. When the secreting cuboidal cells become flattened by milk pressure, milk production stops. Waller²¹ has shown that the careful and judicious use of stilbestrol in the early stages of increased milk tension relieves the pressure and inhibits the onset of the edema, which becomes the obstructing factor. Waller also claims that the prenatal removal of colostrum through manual expression, by the instructed expectant mother, from about the seventh month of pregnancy on, will facilitate the passage of milk through the breasts and lessen the hazard of engorgement. Macneill¹⁹ advises that injured nipples be treated by the early application of hypertonic compresses to painful nipples and the protection of the injured nipples by a soft, rubber, conforming breast shield until the injury is healed.

All recent authors agree that the "rooming-in" system of infant care and "demand feeding" will contribute materially to successful breast feeding as well as satisfy the other postulates. McLendon¹⁸ has laid down for the cultivation of a normal mother-child relation.

A four-bed "rooming-in" unit has been in successful operation at the New Haven Hospital²² for over

a year. Montgomery²³ has used the "rooming-in" system for a number of his private patients in single rooms, with excellent results. In both these groups the mothers were highly selected.

In the private wing of the Boston Lying-in Hospital the "rooming-in" system has been available to mothers scheduled for single rooms for over a year. To date 20 patients have elected this service with but 1 failure. There were nearly 3000 births on the private service during this period, which does not indicate a very great demand. However, more interest in the proposition is evident at present, owing to wide publicity and accelerating interest on the part of the obstetricians. I have no idea how large a proportion of the child-bearing population would elect this system if it were offered to them. Its growth, like that of breast feeding, will depend on prenatal preparation.

On the wards a modification of the "rooming-in" system along the lines of Barnett's²⁴ experience at Los Alamos is planned. It is proposed to keep the babies in the nursery at night but to have the bassinets at the mothers' bedside for the entire day, except for the general visiting hours. So far as possible, the mothers will take complete charge of their babies under expert nursing supervision.

SUMMARY AND CONCLUSIONS

Modern care of the newborn is concerned with attention to factors that may operate before and during birth as well as in the neonatal period. The health and nutrition of the mother from conception on may affect the embryo and fetus and may be responsible for congenital malformations, abortions, stillbirths and premature births. The prenatal period offers the ideal opportunity to prepare the mother psychologically for the nursing and care of her baby.

The major causes of disease in the newborn are anoxic injuries, traumatic injuries, infections, congenital defects and erythroblastosis. Some anoxic injury can be arrested or minimized by improvements in obstetric technic and through the prophylactic use of oxygen. When the anoxic injury is accompanied by generalized edema the administration of fluid is contraindicated. The mortality due to erythroblastosis fetalis has fallen as the result of early delivery in indicated cases with immediate replacement transfusion. If diagnosed promptly, many patients with congenital malformations (such as tracheoesophageal fistulas, absence of the bile ducts, various types of intestinal obstruction and diaphragmatic hernias) now have an excellent chance of being cured by operation. There is good reason to believe that epidemic diarrhea of the newborn can be eliminated through improved nursery technic and the application of simple epidemiologic principles.

Prenatal prophylaxis may reduce the number of premature infants born. Standards and recom-

30355

mentations are available to improve the care of these infants in premature nurseries. A major problem remains — the protection of the premature infant from infection during his nursery stay.

While the infant is in the hospital every effort should be made to lay the groundwork for a future sound mother-infant relation. The cultivation of this relation is helped by breast feeding and the adoption of some modification of the "rooming-in" principle.

on the right. The trachea was displaced to the right side. At the right base posteriorly there was a relatively homogeneous area of increased density, measuring 8 cm in its greatest dimension. There were several radiolucent zones identified in the upper portion of the density (Fig 2). The right leaf of the diaphragm was elevated. There was no obvious obstruction to any of the major bronchi. Bronchoscopy demonstrated a cherry-red lesion in the posterolateral division of the right lower lobe. The patient bled about 70 cc from the site of the biopsy, which on microscopical examination showed only blood clot.

An operation was performed on the seventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR F DENNETTE ADAMS: The history states that "phrenic crush, solganal-B oleosum and bed rest for five months were employed." I start by confronting this audience with a question and asking for a show of hands. How many know what solganal-B oleosum is?

DR DONALD S KING: I know — since yesterday, that is. (Two other hands were raised.)

DR ADAMS: I first scoured the hospital, and then went to work on the telephone. Finally, while I clung to the receiver, Dr King gave me the answer, but he looked it up. Is that correct, Dr King?

DR KING: Yes.

DR ADAMS: It is a gold preparation, which has been claimed to be very good for arthritis and diseases of the lupus group, except acute lupus, and is of doubtful value in tuberculosis. Dr King tells me that certain groups on the continent are investigating the use of gold in tuberculosis.

DR MALLORY: Is there anything in the record about the percussion note of the lungs and fremitus elsewhere than in the upper portions? (I asked about the percussion note and fremitus because that information might help one decide whether he is dealing with solid tumor, fluid, localized empyema or collapse.)

DR TRACY B MALLORY: The percussion note is checked as being abnormal, but that is not explained or amplified.

DR ADAMS: Fremitus is not mentioned except in the right upper lobe?

DR MALLORY: That is correct.

DR ADAMS: Where the sign is the least dependable. Did the patient run a fever during his hospital stay?

DR MALLORY: The temperature was normal throughout, except for a day following the bronchoscopy, when it was 100°F.

DR ADAMS: The diagnosis must be largely based on the x-ray findings. One cannot make it on history or physical signs alone. The patient was sent

into the hospital because of x-ray findings so we may as well see the films now.

In spite of the normal chest film three years before admission, one wonders if, at the start of the illness, the patient did not have lobar pneumonia that lighted up a latent tuberculosis. If the initial episode was tuberculosis, it is inconceivable that he could have been so acutely ill and recovered so rapidly. One could then further postulate that he developed empyema at that time but absence of evidence of fluid in subsequent x-ray films seems to exclude this possibility. So we must start this problem with his second hemoptysis two years and six months following the first acute illness. Dr Wyman, how far back do your films go?

DR STANLEY M WYMAN: About seven months before entry to this hospital.

DR ADAMS: About the time of the second hemoptysis.

DR WYMAN: These films begin seven months before entry to this hospital and show an infiltrative fibrotic area in the right-upper-lung field, with a small amount of similar infiltration on the left. The trachea is displaced toward the right. The right leaf of the diaphragm is slightly elevated in position, possibly owing to the phrenic crush described. There is an ill defined, round shadow of density in the right-lower-lung field. Four months later there is a suggestion of a large area of rarefaction in the center of the lesion, which may have increased slightly in density at the periphery. The next examination, taken about one month after the second, shows a rather clear-cut, round shadow of considerable density centrally, with indefinite, streaky density extending peripherally.

DR ADAMS: Can we stop here for a moment? This first film shows bilateral apical tuberculosis, with a lesion of some sort in the base, which subsequently showed a cavity. Later, this cavity apparently had filled and became invisible. Is that right, Dr Wyman?

DR WYMAN: The central area is denser on the third film. It may be cavity filled with fluid or something that has grown there.

DR ADAMS: Is the third film to be regarded as a healing process compared to the first film? In other words, is it a tuberculous lesion that is becoming fibrotic?

DR WYMAN: I cannot say that. There is no definite wall about the rarefaction as one usually sees in cavities in tuberculosis. This later density is too sharply defined and homogeneous for the usual tuberculous lesion of this sort. I am not able to picture in my own mind how this thing has come about.

DR ADAMS: That makes two of us.

DR WYMAN: The next examination, done three months after the original, shows about the same picture that we see on the first observation. This changes little, if any, at the next examination four

CASE 35021

PRESENTATION OF CASE

A fifty-seven-year-old man was admitted to the hospital after an x-ray study of the chest had revealed a recent infiltration in the right lower lobe

FIGURE 1

The patient was in good health until three years before admission, when chills, fever, dyspnea and hemoptysis of 1 cupful of bright-red sputum appeared. He was given penicillin, and the respiratory symptoms rapidly cleared, but a sense of weakness persisted for several months. X-ray films during the illness showed "scars." The sputum was negative for tuberculosis. Two years before admission he developed a morning cough, productive of a cupful of mucoid sputum, and he became fatigued. Six months later a second hemoptysis

occurred. An x-ray film showed "an apical fibrotic lesion on the right, and a diffuse infiltration at the right base with excavation." The sputum was positive for tubercle bacilli. Phrenic crush, solganal-Boleusum and bed rest for five months were employed. The sputum was positive for two months and then became negative and remained so. X-ray films seven months before admission showed no change in the lesion in the right base (Fig 1). He regained the 25 pounds he had lost prior to hospitalization. He worked for several months but then had several small hemoptyses. X-ray films taken two months before admission showed some spread of the lesion,

FIGURE 2

which was now very pronounced in the right lower lobe. He was given streptomycin for two weeks, but this was discontinued because of nausea. Several chest taps two weeks before admission did not yield any fluid. There had been no recent anorexia, hoarseness, chest pain or weight loss.

Physical examination demonstrated increased breath sounds and tactile fremitus in the right upper posterior chest. Decreased breath sounds were present in the right base. Scattered rales were present in the right axilla. The remainder of the examination demonstrated no abnormalities. The blood pressure was 150 systolic, 85 diastolic.

Laboratory examination showed a normal urine, with a specific gravity of 1.024, a white-cell count of 9700, a hemoglobin of 14.6 gm and a sedimentation rate of 4 mm in 1 hour. Smears of the sputum were negative for acid-fast organisms.

Chest x-ray films showed irregular areas of increased density in both upper lobes, more marked

DR KING You and Dr Davenport agree, but I think I would read tuberculosis in the second film from the left I know the answer, so I am prejudiced

DR WYMAN It looks like it, but the next film does not

DR KING That is true

DR DAVENPORT The cavity is not like tuberculosis

DR WYMAN It does not look like it to me

DR ADAMS But it is a cavity in a patient known to have had tuberculosis That is why I am "hanging my hat" on tuberculosis, but no doubt I have picked the wrong hook

CLINICAL DIAGNOSES

Pulmonary tuberculosis, right upper lobe

Carcinoma, right lower lobe

DR ADAMS'S DIAGNOSIS

Pulmonary tuberculosis, right upper and lower lobes

ANATOMICAL DIAGNOSES

Bronchiogenic carcinoma, right lower lobe

Pulmonary tuberculosis, healed right upper lobe, active right middle and lower lobes

PATHOLOGICAL DISCUSSION

DR MALLORY This is the kind of case to give a clinician whom in the past you have treated very badly

DR ADAMS So you keep on doing the same

DR MALLORY No It is a case on which he cannot be wrong!

This man had both cancer and tuberculosis As you can see from the photograph (Fig 3) the upper lobe is extraordinarily shrunk and consists only of a mass of dilated bronchi embedded in dense scar tissue The present picture is that of localized bronchiectasis In that area I can find neither grossly nor microscopically any evidence of active tuberculosis The middle lobe, in contrast, is considerably enlarged Scattered throughout it are many very small, firm, dense, active tuberculous lesions, but I am afraid they are too small to be visible in the picture The main tumor mass in the lower lobe is a highly differentiated epidermoid carcinoma obviously arising from the lobar bronchus, but all around the tumor, especially toward

the base, is active tuberculosis We do not doubt that he had a cavity, but we did not find any at the time of resection It may well have filled in with tumor

DR ADAMS What was the rationale of operation?

DR LAMAR SOUTTER Dr Sweet operated on him, and our opinion preoperatively was that the

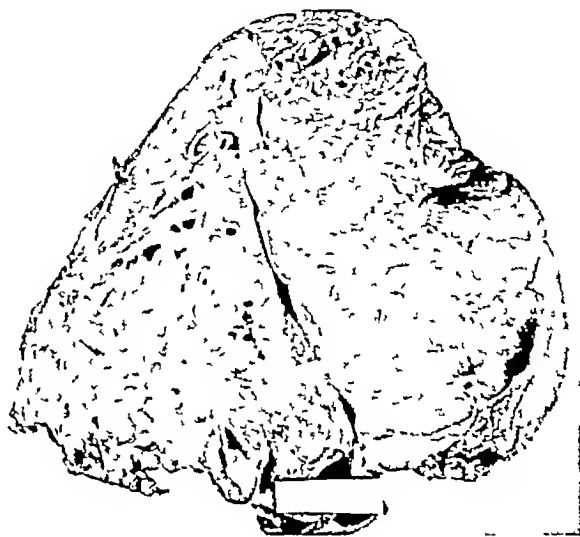

FIGURE 3

patient certainly had tuberculosis We did not believe it was active in the presence of two negative sputum examinations, he had no high temperature, elevated white-cell count and so forth We believed that the most logical explanation for the lesion's increase in size was carcinoma When Dr Sweet opened the chest he thought pneumonectomy was the only possible operation because the amount of tissue left behind would not be valuable Leaving the middle lobe in would be technically difficult and not of any value, and it would be much better to remove the whole lesion

DR WYMAN Was there hemorrhage about the lung adjacent to the tumor?

DR MALLORY Nothing very striking was noted

CASE 35022

PRESENTATION OF CASE

A forty-one-year-old Jewish housewife was admitted to the hospital because of increasing swelling of the abdomen

months later, which is just about three weeks before he entered this hospital. Finally, there is a definite change in the appearance of the lesion, which is now more widely spread, running down to the costophrenic sinus and showing areas of rarefaction in the upper portion.

The bronchi can be fairly well seen. The lateral view shows that the lesion lies in the base of the right lower lobe far posteriorly. I do not know how much the apparent increase in size is due to hemorrhage in and about this lesion.

DR ADAMS: There is no sign of foreign body?

DR WYMAN: Nothing that I can see—no opaque foreign body, at any rate.

DR ADAMS: Are his rib spaces narrowed? Is there any evidence of collapsed lung in the affected area?

DR WYMAN: I do not believe so. One can see the major fissures in the anterior portions of the lungs, suggesting little or no collapse in the lower lobe.

DR ADAMS: It does not look like the picture one sees in coccidiomycosis? Although you say that the cavity wall is thinner than generally seen in tuberculosis, it is not so thin as that which surrounds the cavity of coccidiomycosis?

DR WYMAN: I do not know much about coccidiomycosis.

DR ADAMS: Neither do I, but I have seen some. There is virtually no reaction around the cavity.

Bronchoscopy showed a lesion. But nothing is said about obstruction, and the biopsy demonstrated only blood clot. Following this procedure there was a good deal of bleeding.

I am frank to say that I cannot make a diagnosis. The patient once had active tuberculosis, which was apparently arrested. Then he developed a lesion in the base. At first this must have been regarded as fluid because he was tapped several times. Then he was studied for bronchial obstruction, but no definite evidence of this is recorded. It would be easier if we could presuppose that the high diaphragm was due to collapsed lung, but one cannot assume that it was because the homolateral phrenic nerve had previously been crushed.

Dr King has told me that the effects of phrenic-nerve crush usually endure about six months, in perhaps 15 per cent of cases the nerve may not regenerate at all, provided a thorough crush is done.

DR KING: That is the figure usually quoted.

DR ADAMS: It seems reasonable to assume that the lesion was not collapsed lung secondary to bronchial obstruction or phrenic crush but was in the lung itself. The patient had recently had frequent small hemoptyses. This is not the type of hemoptysis usually seen in tuberculosis. Frequent small hemoptyses bespeak bronchiogenic tumor. We have nothing to substantiate a diagnosis of foreign body. The disease could have been adenoma of the bronchus, it could also have been carcinoma of the bron-

chus. I am relatively certain that the diagnosis was not made prior to operation but that the decision to operate was based on the impression that there was a possibly removable lesion. I can remember in this clinic about a year ago hearing Dr King struggle with one of these cases on which Dr Sweet had operated, my recollection is that both of them said one cannot predict whether a lesion, such as this, is tumor or localized tuberculosis. On the whole, it seems to me most logical to say that this was a tuberculous lesion because we know that the patient had had active tuberculosis. To be sure, no matter which diagnosis one grabs, the answer is always the other. We have a spreading lesion with cavitation in a person known to have had active tuberculosis. We have no definite evidence of bronchial obstruction such as one encounters with adenoma or carcinoma. Cavitation with the two latter is unusual except in the presence of total obstruction. On the other hand the absence of fever and systemic disturbances such as loss of weight and strength is a differential point against active and spreading tuberculosis. Because I have to make a diagnosis, I would put my money, chiefly because the patient has tuberculosis elsewhere, on a tuberculous lesion, but would not be surprised if it turned out to be bronchiogenic tumor.

DR KING: This description of the bronchoscopy worries me. All they say is a "cherry-red lesion." We have no idea about the size, shape or consistency.

DR MALLORY: Did you do the bronchoscopy, Dr Davenport?

DR LOWREY F. DAVENPORT: There was in the posterolateral basal segment of the right lower lobe a small, red lesion, which looked like an adenoma. It was in the bronchus so that it could just be seen faintly, and in grasping the area with the forceps the material was taken out following which there was a gush of blood. The description is not correct. You recall, Dr Mallory, that there were a few cells in the slide, and there was some difference of opinion whether there was enough material to make a diagnosis. It was your opinion that they were tumor cells. I thought from the appearance that probably it was an adenoma, purely because of the bleeding and the suggestive evidence that the bulk of it lay outside the bronchus. Perhaps I was seeing only a small area of infiltrated mucosa with blood clot.

DR KING: Was a study done for tumor cells?

DR MALLORY: Just on the bronchoscopic washings. There were questionable cells mixed in with blood clot from bronchoscopic aspiration.

DR KING: Dr Soutter says that he thinks it was done and was negative.

DR WYMAN: From my point of view I cannot exclude tuberculosis, but I think it is an unusual picture and I had leaned toward tumor, primary bronchiogenic and less likely degenerated adenoma.

safely omit discussion of trauma of the spleen. If the enlargement was not noticed two years before, it must have been a rapidly growing neoplasm. Since it is almost a 75 per cent bet that the findings in this case will be that of metastatic melanotic sarcoma, I think it would be well to review some of the observations about this disease. According to Taylor and Nathanson,¹ this tumor metastasizes early and by way of both the lymphatics and blood stream. In their 265 cases only 25 per cent had five-year cure, 56 per cent of the primary cases had lymph-node metastases, and 74 per cent of the secondary cases had lymph-node disease. Pack,² of New York, finds 50 per cent lymph-node involvement in cases submitted to prophylactic resection. De Cholonky,³ in 1941, studied 117 cases from the New York Post-Graduate Hospital and states "melanoma is invariably fatal if not controlled by surgery" and found metastatic disease occurring anywhere from three months to thirteen years after onset, while death occurred from six months to eleven years. His survival rate was more pessimistic—42.3 per cent for the five-year group but only 9.2 per cent for ten-year survival. Before the pessimistic aspect of this becomes too dismal it might be well to mention 2 cases of personal observation that have survived eight to ten years following a lesion on the fourth toe and another, in a doctor's wife, picked up early on the great toe in which the patient remained well following radical excision of that tumor and groin dissection. It is possible that the patient in the case under discussion had a bizarre finding such as an ovarian cyst on a long pedicle lying in the left upper quadrant. The most likely reason for the operation must have been an attack on the spleen itself or merely exploration for diagnostic purposes.

Unless a totally different neoplasm was discovered at this operation, I would expect the findings to be those of extensive metastatic melanotic sarcoma involving the retroperitoneal area and possibly other abdominal organs. Dr Smithwick had

a case in this hospital recently with a small primary lesion on the right upper arm, autopsy two years later showing the disease involving the lungs, the liver, the kidneys and the small intestine. I do not know of any cases that include splenic involvement, nor did I find any in the literature, but I understand that there is one such case in a male patient in this institution.

CLINICAL DIAGNOSIS

Ovarian cyst?

DR SIMMONS'S DIAGNOSIS

Metastatic melanotic sarcoma

ANATOMICAL DIAGNOSES

Metastatic melanotic sarcoma

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY: It was believed on the wards that there was sufficient possibility that this large abdominal mass was something other than metastatic melanoma to warrant exploratory laparotomy. The patient was operated on with a preoperative diagnosis of "question of ovarian cyst." As soon as the abdomen was opened considerable quantities of serosanguineous fluid escaped through the incision.

As the abdomen was explored great masses of metastatic tumor were found. They appeared to be both retroperitoneal and intraperitoneal, and tumor was present in the omentum, the mesentery and in the liver. Biopsies from several areas all showed malignant melanoma.

Three months before admission the patient noted some discomfort and pain in the left upper quadrant, which occasionally radiated across the abdomen to the right midabdomen. One month before admission she noted an increasing swelling of the abdomen, with a mass in the left side. The mass became acutely tender for a week, and then the tenderness subsided. She gave a past history of having had an appendectomy at the age of twenty-one and an excision of a mole from the abdomen at thirty-one. Six years before entry she had noted some epigastric pain. A gastrointestinal series at that time was reported to be negative. Two years before the present admission she had a pigmented lesion on the lateral aspect of the right ankle excised, and the defect grafted. The lesion measured 1.5 by 3.5 cm in diameter, and the pathological diagnosis was malignant melanoma. There were two questionably enlarged lymph nodes in the right groin, and four weeks later a right radical groin dissection was done. Pathological examination showed no evidence of cancer. At this time there was no evidence of intra-abdominal disease on physical examination. Pelvic examination was not done.

On physical examination the abdomen was protuberant, and there was a huge, fixed, round mass in the region of the spleen. The uterus contained several fibroids. There was no palpable lymphadenopathy. The blood pressure was 130 systolic, 80 diastolic.

Laboratory examination demonstrated a red-cell count of 3,370,000, with a hemoglobin of 9.2 gm, and a white-cell count of 10,400, with a normal differential. The urine was normal. Vaginal smear was negative for tumor cells.

X-ray examination of the abdomen, including a pyelogram, suggested a large, ill defined, intraperitoneal mass in the left midabdomen. The stomach was displaced upward and to the right, as were several loops of small bowel. There was no definite calcification in the mass.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR FRED A. SIMMONS. It would be helpful to know the duration preoperatively of this pigmented lesion. The lesion is described as measuring 1.5 by 3.5 cm in diameter. It occurred to me in reviewing this case that it would often be valuable in these

exercises to have preoperative and postoperative photographs in cases with superficial lesions. These would help characterize the lesion and also aid in evaluating the extent of the operation. This lesion was approximately average in size for a malignant melanoma, since the mean is 3 cm, according to Taylor and Nathanson.¹

A right radical groin dissection was done. It would be valuable to know whether this dissection included removal of the lymph nodes up to the bifurcation of the external and internal iliac vessels. The pathological examination of the nodes showed no evidence of metastasis. A careful search of the current literature and two texts on the subject of cancer failed to emphasize a point that should be brought out here. The disease and other malignant neoplasms often skip the normal distribution into the adjacent nodes, and the disease has often progressed into the abdominal or thoracic cavity while the adjacent lymph nodes are reported to be normal.

It would be of interest to know if the physical examination was done by a medical man or a surgeon, for the medical man often finds spleens that the surgeon does not report. The next sentence implies that the physical examination must have been medical, for it says "no pelvic examination was done." The protuberance may have been due to ascites, but there is no further mention of this. A vaginal smear was negative for tumor cells. I think we may assume that the patient entered this time on the Gynecologic Service.

X-ray examination of the abdomen included a pyelogram. It would be interesting to know if the roentgenologist was willing to express an opinion whether the large mass was intraperitoneal or retroperitoneal. It would be more definitive if "large" could be modified by some measurement. It would be a great help here to have had a barium enema. The absence of calcification would tend to rule out dermoid cyst.

According to previous exercises in this room the negative history of gastrointestinal, genitourinary, gynecologic and neuromuscular systems implies that such history was negative and, therefore, not reported. This leaves us with a lesion that, for lack of any other involvement, must have been retroperitoneal, adrenal or possibly splenic. For the sake of brevity I will omit consideration of the usual medical causes for splenomegaly and can probably

safely omit discussion of trauma of the spleen. If the enlargement was not noticed two years before, it must have been a rapidly growing neoplasm. Since it is almost a 75 per cent bet that the findings in this case will be that of metastatic melanotic sarcoma, I think it would be well to review some of the observations about this disease. According to Taylor and Nathanson,¹ this tumor metastasizes early and by way of both the lymphatics and blood stream. In their 265 cases only 25 per cent had five-year cure, 56 per cent of the primary cases had lymph-node metastases, and 74 per cent of the secondary cases had lymph-node disease. ALPHA AND OMEGA

IN INFANCY and crabbled age an immortality and a fate are presented to mankind. The former, because full of promise, is easier to contemplate and also easier to serve, as witness the readiness with which funds, public and private, are obtained for infant and child welfare, and the increasing scope of effective medical care in this field. As infant mortality has decreased, however, and an ever larger proportion of survivors, healthy to start with, is kept in health, the inevitability of old age increases, but not necessarily its miseries.

In this issue of the *Journal* Clifford recounts the achievements of preventive medicine in the life of the embryo and fetus as well as in the newborn

child. The old wives' tales of a child being "marked" by an experience of the pregnant mother have here modern scientific support. Infections, attempted abortions and poor diet may mark an unborn child with a congenital malformation and may predispose him to the hazards of prematurity or to death by miscarriage or stillbirth. Also, the infant may receive favorable marks from the moment of conception by appropriate medical supervision. In the prenatal period not only are the ill effects of infection, trauma, incompatible blood and inadequate diet prevented but also the mother in a more positive sense may be prepared psychologically for the nursing and care of her child. In this particular the "rooming in" system whereby mother and baby may remain together returns them to the relations of the home and yet affords the scientific protections of the modern hospital.

If babies do not arrive naturally and full-fledged, trailing clouds of glory, but require hard, precise supervision for nine months after the time of conception, neither is the traditional misery of old age as inevitable as supposed. For eight years a geriatric clinic in Boston has been stating the medical problems of old age, asking in what ways health and disease differ in the evening of life and what one does about them. Happily, Monroe, also in this issue of the *Journal*, has made available the benefit of his experience. It appears that, in the second childhood as in the first, nutrition is extremely important, that no play makes these old Jacks the dull boys that they so often are, and that unoccupied old minds like their young counterparts get into slothful or other bad habits.

The extension of individual preventive medicine into the fetal period and the support it gives to certain of Grandma's observations may be viewed with great satisfaction. It is a source of gratification that in lying-in hospitals mother love at last is asserting itself over the nursing supervisor's efficiency and the pediatrician's feeding schedule. It is not so gratifying to realize that one of the few manifestations of filial piety in modern life is the development of geriatrics as a medical specialty, pleasing as it is to contemplate the renewed interest in this phase of medical care.

ARE WAR YEARS GOOD YEARS?

SHORTLY before his death, the late John Winant asked an audience "Are you doing as much for peace as you did for this country and civilization in the days of war?" It is a question well worth pondering. It leads one eventually to consider the incentives for working actively toward peace. Bizarre as it may seem, such incentives do not appear to be very clear in the minds of the American people. To a European whose home was destroyed, whose business was disrupted and who may have been starved, incarcerated, or tortured during the recent war, peace is obviously better than war if only for purely materialistic reasons. To the American who suffered no such privations the evidence that peace is preferable to war may be far less vivid. In fact, according to a recent analysis,* most statistical indexes indicate that war years are more prosperous than peace years. Industrial production, factory employment, hourly earnings and the gross national product all began to rise about 1937 and continued to rise steadily during the war years. They seem to have been influenced little, if any, by the war. The indexes ordinarily used to measure business cycles (bank clearings outside New York City, freight-car tonnage, industrial production, business failures and wholesale commodity prices) show that the periods covered by World War I and II have all the earmarks of prosperity. Public assistance (relief) and business failures declined precipitately from 1940 onward. Business profits, like production, "were greater than usual in the war year 1917, and again the years of the second world war, 1942-45." Indexes, indicative of social conditions, such as marriages, births, deaths and divorces, seem to have been very little affected by the war and certainly were not adversely affected. The statisticians were able to produce very little evidence that war is economically undesirable, although their data do show that taxes and the public debt went up while public works declined during the war years. Nor does their evidence touch on the obvious fact that most of our enormous wartime production was not available or suitable for civilian use.

*Osborn, W., and Adams, J. "Are our wars good times?" *Scient. Monthly* 67:23-33, 1948.

In spite of the incompleteness of purely financial evaluations of the effects of war, such reports unquestionably exert an insidious influence on many people. Confronted with such evidence and recalling his high pay and full employment during wartime what is the American worker to conclude? The businessman also, viewing his increased profits and the seller's market, can hardly regard war as altogether bad. It is perhaps too much to expect these groups to look beyond such statistics and their own wartime business experience to see the unmeasured and perhaps incalculable damage wrought by war on a participating population, no matter how far removed from the actual fighting. The authors of the treatise in question candidly state "The positive association of good times in the United States during the war probably has a bearing upon our willingness to engage in another war." One might put it even more strongly.

Physicians, especially those who served in the armed forces, are in a better position to penetrate the veil of material prosperity and visualize the malignant effects of war. Like the public debt, the disruption of scientific education at all levels and, to some extent, of scientific research will weigh heavily in the future. The vast wastage, not only of materials but especially of scientific talents and skills, was painfully apparent, unavoidable though such wastage may have been. The tangible and intangible effects of wartime fear and insecurity should be apparent to the physician, of all people. These and many more features, whether the statistician's indexes uncover them or not, must ultimately be taken into account by everyone, doctor or layman.

Finally, as the authors point out, this country may not escape vast internal damage if it engages in another war. Whether war can be avoided is problematic. In any case, the country should not enter on any such project without full and sober consideration of the evils of war that business and financial statistics do not reveal. The physician has first-hand knowledge of many of these relatively occult features, and if he does his part to make the layman aware of them, and to keep them crystal clear in his own mind, he can answer Mr. Winant's question with a resounding yes!

child. The old wives' tales of a child being "marked" by an experience of the pregnant mother have here modern scientific support. Infections, attempted abortions and poor diet may mark an unborn child with a congenital malformation and may predispose him to the hazards of prematurity or to death by miscarriage or stillbirth. Also, the infant may receive favorable marks from the moment of conception by appropriate medical supervision. In the prenatal period not only are the ill effects of infection, trauma, incompatible blood and inadequate diet prevented but also the mother in a more positive sense may be prepared psychologically for the nursing and care of her child. In this particular the "rooming in" system whereby mother and baby may remain together returns them to the relations of the home and yet affords the scientific protections of the modern hospital.

If babies do not arrive naturally and full-fledged, trailing clouds of glory, but require hard, precise supervision for nine months after the time of conception, neither is the traditional misery of old age as inevitable as supposed. For eight years a geriatric clinic in Boston has been stating the medical problems of old age, asking in what ways health and disease differ in the evening of life and what one does about them. Happily, Monroe, also in this issue of the *Journal*, has made available the benefit of his experience. It appears that, in the second childhood as in the first, nutrition is extremely important, that no play makes these old Jacks the dull boys that they so often are, and that unoccupied old minds like their young counterparts get into slothful or other bad habits.

The extension of individual preventive medicine into the fetal period and the support it gives to certain of Grandma's observations may be viewed with great satisfaction. It is a source of gratification that in lying-in hospitals mother love at last is asserting itself over the nursing supervisor's efficiency and the pediatrician's feeding schedule. It is not so gratifying to realize that one of the few manifestations of filial piety in modern life is the development of geriatrics as a medical specialty, pleasing as it is to contemplate the renewed interest in this phase of medical care.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CARTER — Arthur C Carter, M D of South Dartmouth, died on November 26. He was in his forty-ninth year.

Dr Carter received his degree from Tufts College Medical School in 1936. He was formerly superintendent of Sassaquin Sanatorium in New Bedford.

His widow, his father and two daughters survive.

CURRIER — W Eugene Currier, M D, of Leominster died on November 23, 1948. He was in his seventy-eighth year.

Dr Currier received his degree from Harvard Medical School in 1898. He was formerly school physician in Leominster and a member of the staff of Leominster Hospital.

His widow and two nephews survive.

GEORGE — Arrial W George, M D, of Wellesley Hills, died on December 25. He was in his sixty-seventh year.

Dr George received his degree from Tufts College Medical School in 1906. He was radiologist at Brooks Hospital, Brookline, Glover Memorial Hospital, Needham, and Massachusetts Institute of Technology. He was a former chancellor of the American College of Radiologists, a member of the New England Roentgen Ray Society, American Roentgen Ray Society and Radiological Society of North America, Inc., and a fellow of the American Medical Association.

His widow, two sons and a sister survive.

OVERLANDER — Charles L Overlander, M D, of Boston died on December 16. He was in his seventy-sixth year.

Dr Overlander received his degree from Harvard Medical School in 1905. He was a member of the American College of Physicians and a fellow of the American Medical Association and was director of the Pathological Laboratory at Brooks Hospital, Brookline.

His widow and a brother survive.

QUIST — F Julius Quist, M D, of Worcester, died on December 20. He was in his seventy-fourth year.

Dr Quist received his degree from Rush Medical College in 1905. He was a fellow of the American Medical Association.

His widow, a brother and a nephew survive.

SILVERSTEIN — Maurice L Silverstein, of Boston, died in the military service on February 16, 1946. He was in his forty-eighth year.

Dr Silverstein received his degree from Boston University School of Medicine in 1923.

MISCELLANY

AWARD TO NATIONAL INSTITUTES OF HEALTH

Dr Rollo E Dyer, director of the National Institutes of Health of the United States Public Health Service, received on December 7, 1948, in behalf of his organization the 1948 Award of Distinction from the American Pharmaceutical Manufacturers' Association in recognition of the Institutes' "great contributions to public health through fundamental medical research for the profound benefit of mankind." Presentation of the award was made by Dr Ernest E. Irons, President-elect of the American Medical Association.

The National Institutes of Health include the National Cancer Institute, the National Heart Institute, the National Institute of Dental Research, the National Institute of Mental Health, the Institute of Experimental Biology and the Institute of Microbiology.

CANCER RESEARCH UNIT AT COLUMBIA

Columbia University has announced its plans for a \$2,000,000 cancer research unit to be constructed on top of the present Vanderbilt Clinic at the Columbia-Presbyterian Medical Center. Half the construction cost will be provided by the National Advisory Cancer Council and half by Columbia University.

AMERICAN COUNCIL ON RHEUMATIC FEVER OF AMERICAN HEART ASSOCIATION

Dr Rustin McIntosh, director of the Pediatric Service, Presbyterian Hospital, and Carpenter Professor of Pediatrics, Columbia University College of Physicians and Surgeons, has been elected 1949 chairman of the American Council on Rheumatic Fever of the American Heart Association.

Mr Lawrence Linch of Chicago was elected vice-chairman.

Newly elected members of the Council's Executive Committee include, in addition to Dr McIntosh, Mr A W Robertson (*ex officio*), chairman of the Board of the American Heart Association, Pittsburgh, Dr Hugh McCulloch, St. Louis, Dr Walter Bauer, Boston, Dr David D Rutstein, Boston, Dr Edward Harmon, Valhalla, New York, Dr M J Shapiro, Minneapolis, Dr T Duckett Jones, New York City, Dr Homer F Swift, New York City, and Dr George M Wheatley, New York City.

QUARTER, QUARTER, WHO HAS THE QUARTER?

S 1520 [Wagner-Murray-Dingell Bill], Section 204

(a) Every individual shall be eligible for benefits under this title throughout any benefit year if —

(1) he has received (or, in the case of incomes from self-employment, has accrued) —

(A) not less than \$150 in wages during the first four of the last six calendar quarters preceding the beginning of the benefit year, or

(B) not less than \$50 in wages in each of six calendar quarters during the first twelve of the last fourteen calendar quarters preceding the beginning of the benefit year (not counting as one of such fourteen calendar quarters any quarter in any part of which the individual was under a total disability which continued for six months or more),

(2) he is entitled, for the first month in the benefit year, to a benefit under title II of the Social Security Act, as amended, or to an annuity under the Civil Service Retirement Act, as amended, or

(3) he is on the first day of the benefit year a dependent of an individual who is eligible under paragraph (1) or paragraph (2).

OUTPATIENT TREATMENT OF VETERANS

Nearly 2,000,000 veterans received outpatient treatment from the Veterans Administration during the fiscal year ending June 30, 1948. The treatments were given at regional offices, hospitals and clinics, and by private physicians co-operating with the Veterans Administration in providing home-town care for veterans with service-connected disabilities.

Treatments averaged 3 per veteran, or a total of 5,223,680. Patients treated numbered 1,937,842.

Private physicians treated 761,185 veterans, or about 40 per cent of the total. The physicians were paid \$11,437,870 for 2,735,450 treatments, or an average of \$4.18 per treatment or \$15.03 per veteran undergoing medical care.

Veterans Administration staff doctors during the year treated 1,176,657 individual veterans, providing a total of 4,498,230 treatments.

CORRESPONDENCE

HISTOPLASMIN REACTIONS

To the Editor The publications concerning histoplasmosis have proved the importance of this interesting infection. Up to this time we at the Wrentham State School have had no possibility of publishing our experiences.

In the fall of 1946, we were supplied with a small amount of extract by Dr Herman Vollmer. In our first series 0.1 cc of a solution of 1:1000 was administered intracutaneously to 200 patients, 2 of whom showed, on the third day, a mild local reaction, which disappeared on the fourth day. One of them had a positive Pirquet reaction. In the other, a seventeen-year-old boy, the Pirquet reaction was negative, and x-ray examination showed a peculiar appearance of the lungs, resembling tuberculosis.

SURVEY OF MEDICAL EDUCATION

BEGINNING with the new year, the Council on Medical Education and Hospitals of the American Medical Association and the Association of American Medical Colleges have put on foot a three-year joint survey of medical education in the United States. To further this project a committee of seven has been appointed, composed of leaders in medical education, and Dr. John E. Detrick, of New York, has been selected as the full-time director of the survey. Dr. Detrick, a graduate of Johns Hopkins University School of Medicine, is associate professor of medicine at the Cornell University Medical College, and medical director and director of postgraduate instruction of the Second Medical Division, Bellevue Hospital.

The objects of the study, as stated by the committee, are to evaluate the present programs and determine the future responsibilities of medical education in its broadest aspects, in order to improve medical education better to meet the needs of the American people for the prevention of disease, the expedition of convalescence and the maintenance of health, to assess the degree to which medical schools are meeting the needs of the country for physicians, to promote the advancement of knowledge in the field of medical science, and to inform the public concerning the nature, content, and purposes of medical education.

The present survey is the third that has been made in forty years. The first resulted in the Flexner Report, published in 1910 by the Carnegie Foundation for the Advancement of Teaching, the second resulted in the Weiskotten Report, published ten years ago.

This timely survey will undoubtedly consider various factors that concern the future of medical education—the problem of preparedness for national emergencies, the social aspects of medicine in all their ramifications, the place that medical practice will occupy, and the sources of the funds with which the costs will be defrayed.

The world has become a social laboratory in which medicine must play its part in interpreting the reactions

HISTOPLASMOSIS IN MASSACHUSETTS*

PREVIOUSLY in these columns* mention was made of the possible significance of histoplasmosis as the cause of the unexplained cases of disseminated areas of calcification visible in x-ray films of the lungs in nonreactors to tuberculin who give positive skin reactions to histoplasmin. Attention was called to the recent surveys, particularly those carried out in Kansas City, Missouri, and in Tennessee, which uncovered a large number of such persons. Studies among nurses also revealed a high incidence in the eastern central area of the United States, and the frequency of their occurrence diminished progressively in proportion to the distance from this area. It was noted at that time that histoplasmosis was not known to occur in New England but that it had been reported from areas as close as New York and Washington, D. C.

In a letter from Mautner, which appears elsewhere in this issue of the *Journal*, evidence is presented suggesting that infections with histoplasma might indeed occur in an unrecognized form in Massachusetts. The evidence, to be sure, is far from conclusive. It is based upon the demonstration of local reactions in the skin of patients at the Wrentham State School following intracutaneous injection of histoplasmin. Of 200 patients tested with 0.1 cc. of a 1:1000 dilution, only 2 showed mild reactions that were delayed, and injection of a larger amount—namely, 0.1 cc. of a 1:100 dilution—yielded 19 reactors among 100 patients, and the reactions were more intense and occurred earlier. All but one of the histoplasmin reactors showed positive tuberculin tests. The negative tuberculin reactor who was tested with the smaller amount, and 4 of those who reacted to the larger amounts of the histoplasmin showed some areas of pulmonary calcification in roentgenograms of the chest. Mautner's findings, though inadequately controlled and not proving conclusively that his reactors had histoplasmosis, suggest that this infection should be considered in the differential diagnosis of patients with diffuse pulmonary lesions in which other more likely diagnoses can be ruled out.

*Editorial. Nontuberculous pulmonary calcification. *New Eng. J. Med.* 237:171, 1947.

The author, in this short monograph, presents 47 cases of chronic disease relieved by drainage of the nasal sinuses. The diagnosis of the condition was made largely through an intensive study of the fields of vision. A short bibliography and a list of cases conclude the text. There is a good index. The publishing is excellent. The price is reasonable. The volume should prove interesting to ophthalmologists and rhinologists.

Modern Trends in Dermatology. Edited by R M B MacKenna, M A, M D (Camb), F R C P (Lond), physician-in-charge, dermatological department, and lecturer in dermatology, St Bartholomew's Hospital, London physician to St. John's Hospital for Diseases of the Skin, London honorary consultant in dermatology to the British Army and examiner in dermatology, Royal Army Medical College. 8° cloth 432 pp, with 32 illustrations. New York: Paul B Hoeber Incorporated, 1948. \$5.50.

This composite work of twenty-three dermatologists presents the modern conception of dermatology in varying aspects. The first chapter constitutes a short history of dermatology, followed by special chapters, including psychologic aspects, problems in tropical and subtropical areas, the prevention of cutaneous diseases (excluding industrial diseases) and the rehabilitation of dermatologic patients. The question of rehabilitation has received needed attention only recently. Bibliographies are appended to the chapters. The type and printing are good, but the use of a coated paper is not justified by the few noncolored illustrations. The volume is recommended for all medical libraries.

The Scientific Paper. How to prepare it, how to write it. A handbook for students and research workers in all branches of science. By Sam F Trelease, Columbia University. 12° cloth, 152 pp, with 8 illustrations, 7 tables. Baltimore: The Williams and Wilkins Company, 1947. \$2.00.

This is a new edition of the author's *Preparation of Scientific and Technical Papers* published in 1936. The text has been thoroughly revised and largely rewritten. The manual is intended for students and research workers but should prove valuable to physicians who are called on to write papers for publication. It covers the whole field from outlining and writing the paper to proofreading. A good index concludes the volume. It is recommended for all medical libraries.

Medical Hypnosis. Vol I. The Principles of Hypnototherapy. Vol II. The Practice of Hypnototherapy. 8°, cloth, Vol I 449 pp, Vol II, 513 pp. New York: Grune and Stratton, 1948. Vol I, \$5.50, Vol II, \$6.50.

This comprehensive treatise covers the whole field of hypnotherapy. The second volume is devoted to discussions of hypnosis in the removal of symptoms, in psychologic therapy and in psychoanalytic therapy. The work is well published. The set is recommended for large medical libraries and to psychiatrists.

The Skull, Sinuses and Mastoids. A handbook of roentgen diagnosis. By Barton R Young, M D, professor of radiology, Temple University Medical School. 8°, cloth, 328 pp, with 141 plates. Chicago: The Year Book Publishers, Incorporated, 1948. \$6.50.

This volume is one of a series of handbooks on x-ray diagnosis projected by the publishers. The text is divided into three parts: the skull, the nasal sinuses and the mastoids. The text comprises descriptions of various conditions each of which is illustrated with a radiographic plate. The type, printing and plate work are good. A bibliography and a good index conclude the volume. The seemingly large price is justified by the large number of plates. This volume and its companions should be in all medical libraries and in the libraries of radiologists.

The Diabetic's Handbook. How to work with your doctor. Treatment by diet and insulin. By Anthony M Sindoni, Jr, M D, chief, Department of Metabolism, Philadelphia General and St. Joseph hospitals, chairman, Advisory Committee on Dia-

betes to director of Department of Public Health, Philadelphia and chief diseases of metabolism, St. Francis Hospital, Wilmington Delaware. With an introduction by Rufus S Reeves, M D, director, Department of Public Health, Philadelphia. With a foreword by Charles C Wolferth, M D, professor of medicine, School of Medicine, and administrator of the Robinette Foundation for Research in Cardiovascular Disease, University of Pennsylvania, director for cardiology, Professional Services Division, Veterans Administration and consultant cardiologist to the Jewish Hospital. 5° cloth 194 pp. New York: The Ronald Press Company, 1948. \$3.00.

This manual for the diabetic patient is the joint work of seven physicians. The material is well written and well organized. The section on foods, documented with a number of tables, comprises sixty-three pages. A good index concludes the volume. The book is well published and should prove useful to patients and their families.

Intracranial Tumors. By Percival Bailey, M D, professor of neurology and neurological surgery, University of Illinois. 8° cloth 471 pp, with 153 illustrations and 16 plates. Second edition. Springfield, Illinois: Charles C Thomas, 1948. \$10.50.

This second edition of an authoritative treatise has been revised to include the recent advances in knowledge, and a brief atlas of roentgenographic photographs has been added as an appendix. A comprehensive bibliography concludes the text. There is a good index. The volume is well printed with good type on lightweight, nonglare paper. It is recommended for all medical libraries.

NOTICES

ANNOUNCEMENT

Dr Arthur L. Hanraban announces the removal of his office from 45 Bay State Road to 270 Commonwealth Avenue, Boston, for the practice of surgery.

GEORGE F BAKER CLINIC

The Committee on Diabetes, appointed by action of the Massachusetts Medical Society, has suggested that clinical exercises in diabetes be offered without charge in various hospitals for physicians. To this end the George F Baker Clinic at the New England Deaconess Hospital offers exercises on Monday and Friday of each week. The schedules are as follows:

Monday, 8:00-9:00 a.m., Second Floor, New England Deaconess Hospital. Case Presentations in Diabetes and Surgery of the Extremities.

Friday, 8:00-8:15 a.m., Second Floor, New England Deaconess Hospital. X-Ray Pathology in Diabetes.

8:15-9:00 a.m. Classroom, George F Baker Building. Case Problems in Treatment of Diabetes and Complications. Pregnancies, acidosis, insulin resistance and so forth.

9:00-10:30 a.m. Medical Rounds for Visiting Physicians.

9:00-10:30 a.m. Instruction in Diet and Urine Testing (for Office Nurses, Technicians or Secretaries Sent by Physicians).

10:30-11:15 a.m. Class Teaching in Diabetes (Physicians, Office Assistants and Nurses are welcome).

SOUTH END MEDICAL CLUB

A regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, January 18, at 12 noon. Dr Lawrence C Kingsland, Jr, will speak on the subject "Respiratory Infections in Children." The lecture will be illustrated with lantern slides. All physicians are cordially invited. Luncheon will be served after the lecture at a cost of 60 cents. Reservations should be made for the luncheon.

In January, 1947, we were supplied with a stronger extract of 1 100, 01 cc of this solution was administered to 100 patients. Nineteen showed a local reaction on the following day. In 9 of them the reaction was quite strong, but only 6 were positive on the next day. All 19 patients showed a positive tuberculin reaction. X-ray films of 4 showed calcification of the lung, which could easily have been Ghon nuclei or calcified lymph nodes. One film even looked somewhat peculiar for tuberculosis.

The examinations have not been continued, since it was difficult to obtain the extract at that time. Nevertheless, it seems that isolated infection with histoplasma, without severe sequel, occurs in Massachusetts.

The patients examined were in the care of the Wrentham State School, and the last series of 100 were in a building where the older women live.

HANS MAUTNER, M D

Wrentham State School

HOW TO MAKE FRIENDS AND INFLUENCE PEOPLE

To the Editor The following safe advice, presented to the meeting of secretaries and editors at St. Louis, speaks for itself.

FRISCO DOCTOR PRESENTS HIS OWN PROGRAM In this day and age when everybody is talking himself hoarse about medical plans and programs, Dr. Anthony B. Diepenbrock, of San Francisco, comes up with his own 13-point health program which, he says, "might be interesting to our colleagues."

1 Continue to sit on your fat derriere and do nothing.

2 Be apathetic and, like 5,000,000 registered Republican voters who failed to vote, do not bother to make your opinion known. If you think, as they did, that your opinion or your vote is not worth anything, the opposition will agree with you and act accordingly, as they have.

3 Write an occasional letter to your congressman, tell him off, and then explain proudly to the intern in the surgical dressing rooms how smart you are and what a stinker your congressman is.

4 Tell everybody you see that the gag is up, and we might as well prepare for the inevitable.

5 Moan and groan and issue explosive and unprintable epithets.

6 Refer to your medical leadership as a group of impotent, ineffective and bumbling ignoramuses.

7 Make speeches before sympathetic lay audiences, and convert those who already believe in free enterprise.

8 Don't bother to tell your county society heads, your state society heads, or your national association heads what you want them to do. Expect them to find a way for you without your guidance.

9 Scream about high medical society dues and forget that our friends in the trades unions demand many times what we pay. In other words, make the situation as difficult as possible, then grumble about it.

10 Oppose any program developed by the majority of your colleagues because it demonstrates your superior wit and your general greatness.

11 Remain superbly and learnedly dignified when Joe Doakes asks why you oppose state medicine. Brush him aside with any insult you can think of. Joe will like you for that.

12 Don't bother to use the selling methods which actually bring messages before the public. Continue to depend on occasional radio feature programs. Billboard advertising, newspaper advertising, national magazine advertising, radio advertising and above all, continuous and daily radio spot programs over national hookups and all such like are too commercial, too troublesome, too expensive and too undignified don't use them.

13 Above all, disregard the "little guy" — the one with a vote. Tell him nothing, push him around. He doesn't know anything anyhow.

H. QUIMBY GALLUPE, M D

8 Fenway, Boston

SOUTH CAROLINA LEADS

To the Editor In the December 2 issue of the *Journal*, I read with interest your editorial on the Massachusetts Medical Benevolent Society, "the oldest of its kind in continuous existence in the United States," calling attention to its ninety years of useful and beneficent activities. I now respectfully direct your attention to Charleston, America's Most Historical City, where, on January 12, 1949, The Society for the Relief of the Families of Deceased and Disabled Indigent Members of the Medical Profession of the State of South Carolina, today referred to as the Widows and Orphans Society, is having its Centennial Banquet. In its early days the treasurer's books carry the name of the Medical Benevolent Society. The Society was organized in 1848 and was incorporated on December 19, 1849. Annually, it has contributed to its beneficiaries. One reason for its continued growth is a wise provision in the Constitution to the effect that a fourth of the annual income must be reinvested. According to its Constitution "any person of good moral character" may be a member. "The members of the Society shall annually assemble and dine or sup together, in the City of Charleston, on the second (2nd) Wednesday of January in every year." The Stewards are to provide and the Treasurer is to pay for the supper.

LEON BAYOV, JR., M D

1041½ Rutledge Ave.,
Charleston 16, S C

Note: Apologies and congratulations to the medical fraternity of South Carolina — Ed

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

War, Politics, and Insanity. By C. S. Bluemel, M A, M D, M R C S (Eng). 8°, cloth, 121 pp. Denver: The World Press, Incorporated, 1948. \$2.00.

The author in this monograph discusses the psychological qualities of political leadership and the disorders of personality with which aggressive leadership is commonly associated.

Modern Clinical Psychiatry. By Arthur P. Noves, M D, superintendent, Norristown State Hospital, Norristown, Pennsylvania. Third edition. 8°, cloth, 525 pp. Philadelphia: W. B. Saunders Company, 1948. \$6.00.

This third edition of a textbook, first published in 1934 and revised in 1939, has been largely rewritten, and three chapters have been added on psychotherapy, shock and other physical therapies and child psychiatry. The material on the psychoneuroses has been amplified, and that on psychosomatics has been extended. The book is based on lectures originally presented to senior medical students. The material is well organized and well written, and the publishing is excellent.

Subacute Bacterial Endocarditis. By Emanuel Libman, M D, and Charles K. Friedberg, M D, adjunct physician, Mt. Sinai Hospital, New York City. Edited by Henry A. Christian, A M, M D, LL D, Sc D (Hon.), M A C P, Hon. F R C P (Can.), D S M (Am. Med. Assoc.). 8°, cloth, 113 pp., with 19 illustrations. New York: Oxford University Press, 1948. \$3.50. Reprinted from *Oxford Loose-Leaf Medicine* with the same pagination.

This monograph is a reprint from the *Oxford Loose-Leaf Medicine*, published in book form, making it available to interested physicians who do not have the system. The text reflects the latest information on the subject. A large bibliography concludes the text. The publishing is well done.

Chronic Ill-Health, Relieved by Drainage of the Para-Nasal Sinuses. By Rosa Ford, M B (Lond.), D O (Oxon). 12°, cloth, 104 pp., with 13 illustrations. London: Henry Kimpton, 1948. 6/6 net.

GASTROJEJUNOCOLIC FISTULA*

Review of Nine Cases, with Use of Vagus Resection as Part of the Operative Procedure in One

HENRY H. FAXON, M.D.,† AND WILLIAM G. SCHOCH, JR., M.D.‡

BOSTON AND FRAMINGHAM, MASSACHUSETTS

GASTROJEJUNOCOLIC fistula following gastrojejunostomy has long been considered one of the most serious complications of gastric surgery. Historically, the initial reports on the evolution and correction of the condition include the description by Wolfer of the first gastroenterostomy in 1881, the recognition by Braun of a gastrojejunal ulcer eight years later, the finding by Czerney¹ of a fistula into the colon at the site of a previous gastroenterostomy in 1903, and the surgical intervention for the correction of the condition by de Herzele² in 1905.

The surgical problem is solved by removal of the fistula, restoration of bowel continuity and correction of the ulcer diathesis. Because vagus resection has not been reported as the method of dealing with this last factor a case from the Cushing Veterans Administration Hospital is cited in which it was successfully employed after restoration of the continuity of the intestinal tract, and the data on 8 other cases of gastrojejunocolic fistula from the Massachusetts General Hospital are added.

INCIDENCE

In 1941 Bornstein³ reviewed the literature and found only 322 cases of gastrojejunocolic fistula, thus suggesting that the experience of any one surgeon in treating the condition must of necessity be limited. In the past forty years there have been but 18 such patients admitted to the Massachusetts General Hospital,^{4, 5} and no case has been encountered since 1941. The decreasing incidence can be explained chiefly by the steadily growing enthusiasm

for gastric resection rather than gastroenterostomy in the treatment of duodenal ulcer. The extent to which this shift in the surgical approach has taken place is illustrated by a threefold increase in resections for duodenal ulcer at the Massachusetts General Hospital during recent years, as contrasted with the near disappearance of the operation of gastrojejunostomy alone (Fig. 1). Vagus resection has also been adopted during the last four years as another method of surgical treatment of an appreciable number of patients.

It is far from true, however, that gastrojejunocolic fistula can now be considered an obsolete entity. Because of the long interval between gastroenterostomy for ulcer and the occurrence of fistula (Table 1) there is bound to be a continuing residue of such fistulas for an appreciable period. Furthermore, some surgeons still perform gastroenterostomies without resection for duodenal ulcer, thus establishing the potential origin of a gastrojejunocolic fistula. In addition, partial gastric resections that inadequately control the ulcer diathesis may produce marginal ulcers, which subsequently involve the colon. Finally, during what must be considered the experimental phase in the era of evaluation of vagus resection with associated gastroenterostomy, as advocated by Dragstedt et al.⁶ in the treatment of duodenal ulcer, there will be a certain number of cases in which the resection of the vagi will not be permanently effective in altering gastric acidity because of either an inadequate original operation or a possible subsequent regeneration of nerve fibers. Such patients will then present essentially the same anatomic background for fistula formation as those of the earlier period, on whom gastroenterostomy alone was carried out.

ETIOLOGY

Gastrojejunal ulcer is the inevitable precursor of a gastrojejunocolic fistula but the exact cause of such an ulceration remains as much a matter of debate as the etiology of the duodenal or gastric

MT AUBURN HOSPITAL

The following public-health lectures will be held at Margaret Jewett Hall, Mt Auburn Hospital, 330 Mt Auburn Street, Cambridge, Massachusetts, on Wednesday evenings at 8 o'clock

- January 19 X-Ray in Modern Medicine Richard Schatzki, M D
 February 2 The Cancer Problem Edward A Cooney, M D
 February 16 The Heart and High Blood Pressure Dudley Merrill, M D
 March 2 Tuberculosis Lowrey F Davenport, M D
 March 16 Surgical Emergencies Stanley J G Nowak, M D

These lectures are open to the public

NATIONAL CONFERENCE ON MEDICAL SERVICE

The National Conference on Medical Service will be held at the Palmer House, Chicago, on February 6. The preliminary program is as follows

- 9 00 a m Registration, Foyer of Red Lacquer Room Fourth Floor Palmer House
 9 30 a m Call to order
 Appointment of Committees
 Address of the President — E F Sladek, M D, Traverse City, Michigan
 9 45 a m Legalized Medical Research
 Medical Problems — Chris J D Zarafonetus, M D, University of Michigan
 Legal Problems — George Wakerlin, M D, University of Illinois
 10 25 a m Title to be announced — James R McVay, M D, Kansas City, Missouri, Chairman, Council on Medical Service, A M A
 10 50 a m Progress of the World Health Organization — Frank Calderone, M D, Director, American Office, World Health Organization
 11 05 a m Progress of the World Medical Association — Creighton Barker, M D, Executive Secretary, Connecticut State Medical Association
 11 20 a m Medical Program of the United Mine Workers of America Welfare and Retirement Fund — Warren F Draper, M D, Executive Medical Director
 11 40 a m Discussion Period
 12 15 p m Subscription Luncheon
 1 00 p m The A M A puts on its Fighting Togs Speaker to be announced
 2 00 p m What's Happening in Washington This Week — James D Boyle, United Public Health League
 2 30 p m Discussion To be opened by Joseph S Lawrence, M D, Director of the Washington Office, A M A
 2 40 p m Panel Discussion on Postgraduate Education of the Doctor —
 (a) Responsibility of Medical Schools in Continued Postgraduate Education of the Doctor — George N Agaard, Director of Postgraduate Medical Education Program, University of Minnesota
 (b) Function of the State Medical Society in Postgraduate Work — C W Smith, M D, Harrisburg, Pennsylvania
 (c) Survey Findings on Specialization in Colorado — Harold I Goldman, M D, Denver, Colorado
 3 40 p m Discussion Period
 4 00 p m Can Corporations Such as Hospitals Legally Engage in the Practice of Medicine? — Wilbur Bailey, M D, Los Angeles, California
 4 30 p m Report of Committees and Election of Officers
 5 00 p m Adjournment
 (Note All papers will begin exactly as scheduled No speaker will be allowed to speak overtime)
 All physicians are invited

THE AMERICAN CANCER SOCIETY FELLOWSHIPS IN EXFOLIATIVE CYTOLOGY

At the symposium on exfoliative cytologic diagnostic techniques of the American Cancer Society, held in Boston in April, 1948, the opinion was expressed that facilities were urgently needed to train qualified pathologists and clinicians in teaching positions at approved institutions providing residency training in pathology as well as facilities for the training of technicians

At the same time delegates recommended that the American Cancer Society proceed to engage actively the interest and support of institutions and laboratories in setting up such training programs where the best training facilities appeared to be available. Thus inquiries were sent to four teen laboratories over the country and, on the basis of their interest and monies available, grants will be made for fellowship training in ten laboratories to support 23 fellows

The purpose of these fellowships is to provide training in diagnostic techniques in exfoliative cytology for qualified pathologists. It is anticipated that trainees will not assume the role of teachers until sufficient personal experience and competence have been acquired

Fellowships shall be awarded by institutions or laboratories designated by the Society to applicants on the basis of their past training and their intention to teach in their own laboratories diagnostic techniques in exfoliative cytology to interested pathologists, clinicians and technicians

Applicants for fellowships in exfoliative cytology of the American Cancer Society shall be graduates of Class A medical schools of the United States and its territories and of Canada, and be citizens of the United States not over fifty years of age on the next birthday following commencement of fellowship tenure. They shall have completed two years of postgraduate training in pathology and shall conform in other respects to requirements of the institution to which they apply

Each fellowship shall be awarded for a period of four months. Fellowship training shall begin on November 1, 1948, or as soon as possible thereafter. Such fellowships are not subject to renewal

Stipends will be paid in two sums: the first, a grant to the laboratory for tuition, overhead, and other expenses as outlined to the Society; the second, to the trainee partially to cover his board, room and incidentals for the period of training. The latter sum shall amount to \$140 and shall be paid directly to the recipient monthly in advance to avoid payment of income tax for services rendered to the hospital

Individual applicants for fellowships in exfoliative cytology shall apply directly to institutions where fellowships are available. In no instance shall application be made directly to the American Cancer Society

The following fellowships are available

partial obstruction and dilatation proximal to the fistula

An interesting feature of the lesion is that, as a rule, unless the fistula is very large the folds of jejunal mucosa act as a valve that prevents passage of gastric contents into the colon via the fistula^{3 24} (Fig 2) but permits the regurgitation of feces and flatus into the jejunum and thence into the stomach. This explains the greater efficacy of barium enemas as compared to barium by mouth for visualizing these fistulas and further suggests why medications are ineffective in combating the diarrhea,

symptoms usually started in their late twenties, were over forty-five years of age before they were operated on for the fistulas (Table 1)

Weight loss is the most consistent symptom in gastrojejunocolic fistulas (Table 2), being marked and rapid in over 90 per cent of the cases in spite of the fact that anorexia is uncommon. Except in patients with fecal vomiting,²⁴ unimpaired or even increased food intake is the rule.³ Thus, although the appetite in 3 cases was better than usual, and decreased in but 1, 8 patients were strikingly below their normal weight. This weight loss is primarily the result of the watery or semisolid diarrhea found in two thirds of this series, but usually encountered in an even higher proportion.¹⁶ The stools are acid and foul, owing to fatty acids, and, on occasion (as illustrated in 1 of our cases), show recognizable undigested food within an hour of its ingestion. Further manifestations of the diarrhea in two thirds of the cases are weakness, dehydration and emaciation.^{3 16} Lowered serum protein values in over 80 per cent

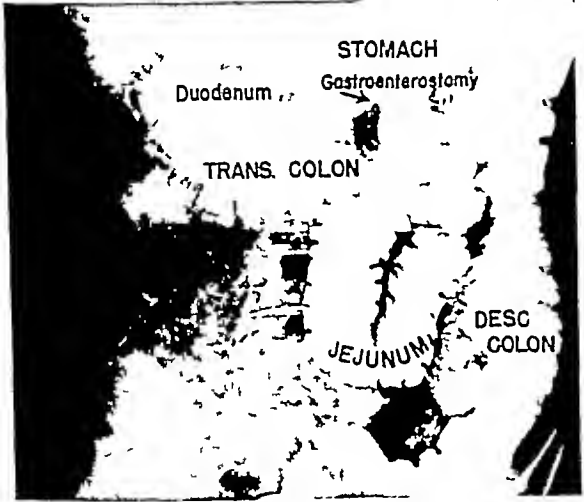

FIGURE 2 Roentgenogram Demonstrating Stomach Filled with Opaque Material after a Barium Enema. No barium passed through the fistula in the reverse direction after gastric studies

whereas a constipating diet is sometimes successful. The mechanism of the diarrhea, with its resulting loss of weight, vitamin deficiency and hypoproteinemia, therefore, is probably irritation of the small intestine by feces and not, as is commonly believed, the direct and rapid passage of gastric contents into the colon.

CLINICAL DATA

All patients were men whose original lesion was a duodenal ulcer. They were first operated on at an average age of thirty-four, approximately five years after their first symptoms, 6 posterior gastroenterostomies, 1 pylorotomy, 1 exclusion operation and 1 Billroth II were the original procedures. An average of nine years supervened before ulcer symptoms recurred, and on the average two years were added before symptoms of a fistula became evident. Even then the symptoms were allowed to persist for approximately a year before operation was carried out, so that these patients, whose ulcer

of the cases are reported by Atwater, Butt and Priestly.¹⁶

About half the patients complained of fecal-smelling eructation,^{16 26} which was a more common finding than foul vomiting, since the passage of gas into the stomach from the colon takes place more readily than intestinal material and does not depend to the same degree on the fluidity of the large-bowel contents.³ Nausea and vomiting were present in 5 cases but both were not always present in the same patient. In the absence of intestinal obstruction, vomitus that is fecal in character is pathognomonic of a gastrocolic fistula.

Hematemesis occurred in 3 patients, 2 of whom also showed melena. A somewhat lower incidence was reported by Gray and Sharpe,²⁶ who found gastrointestinal hemorrhage in 30 per cent of gastrojejunal ulcers before a fistula had formed and 10 per cent after the fistula had become evident. Such bleeding is the chief cause of the varying degree of anemia found in over 50 per cent of the cases,¹⁶ although the generally debilitated state of the patients and their markedly altered nutrition undoubtedly also contribute to this finding. Gastric acidity studies are variable and of little diagnostic help, since bile and proximal jejunal contents inter-

ulcer that preceded it. It seems probable that anastomotic ulcers occur when enterostomy or gastric resection fails to control adequately the gastric hyperacidity in a patient with an ulcer diathesis.⁷ The lesions represent the effect in such persons of the unneutralized acid gastric contents on the first part of the small intestine with which they come in contact. Operations for gastric ulcers

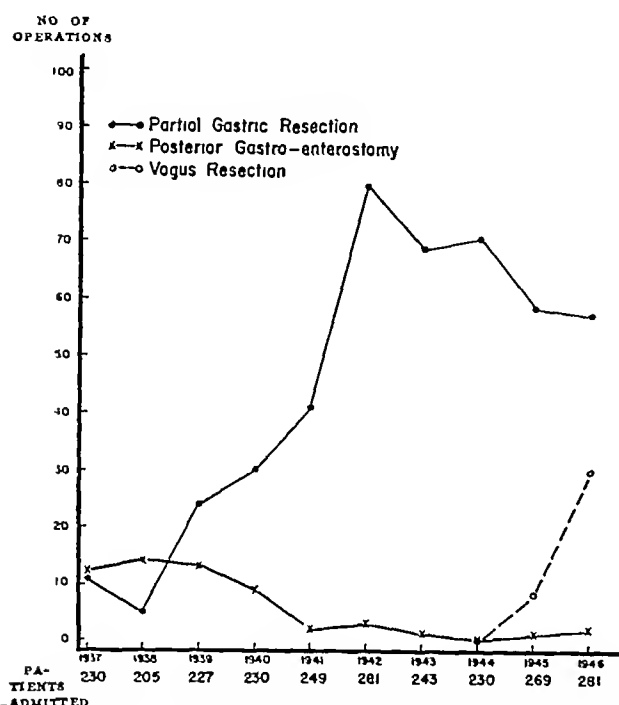

FIGURE 1 Types of Operation for Duodenal Ulcer at the Massachusetts General Hospital, 1937-1946, Showing the Increase in Gastric and Vagus Resections and the Decrease in Gastroenterostomy as the Surgical Treatment of Duodenal Ulcer

A total of twenty-four other types of gastric operations, including plastic procedures and explorations, were done during this period

are seldom attended by this complication, in contradistinction to those for duodenal ulcers.³

The incidence of gastrojejunal ulcers after gastroenterostomy alone varies according to different authors⁸⁻¹⁰ from Verbrugge's⁸ figure of 1.41 per cent to Hurst and Stewart's¹⁰ 51 per cent. Balfour and Down¹¹ report a rate of 3.26 per cent of 500 cases, and Benedict⁵ cites a comparable figure from the Massachusetts General Hospital of 2.9 per cent.

After gastric resection for benign lesions, the incidence of gastrojejunal ulcers is at the lower rate of 0.4 to 10 per cent,¹²⁻¹⁵ and marginal ulcers are essentially never encountered in resections for gastric carcinoma, in which condition hypochlorhydria is the rule. Between 8.7 and 23.8 per cent^{7, 16-22} of all marginal ulcers perforate into the transverse colon, causing gastrojejunal fistulas.

The time between the original operation for ulcer and the development of a fistula varies from six

weeks to forty years,^{3, 23} with an average of approximately seven years.^{3, 16, 24} The 9 patients in the present series averaged eleven years (Table 1).

Inasmuch as duodenal ulcers are approximately four times as common in male as in female patients,²⁵ it is not surprising that marginal ulcers, which represent a secondary surgical complication to the condition, are relatively rare in women and that gastrojejunal fistulas as a further sequela are almost never encountered.

At the time the diagnosis of gastrojejunal fistula was made the average age of our 9 patients was forty-four years, which closely parallels the average reported in larger series of cases,^{3, 26} and the individual variation of thirty-one to fifty-eight years in our cases likewise approaches the span of twenty to seventy-two years found in the literature.^{8, 24}

In the period covered by this paper (1937-1947, inclusive) 5 patients were admitted to the Massachusetts General Hospital in whom gastrocolic fistulas were due to carcinoma, 1 originating in the stomach and the other 4 in the colon. These

fistulas as well as those secondary to tuberculosis and other special diseases of the stomach or colon^{7, 16, 22, 27} are caused by simple direct extension of the pathologic process rather than by any alteration in gastric physiology and are, therefore, not included in the present discussion.

PATHOLOGY

Depending on the site and extent of the anastomotic ulcer, the fistula may be gastrocolic, jejuno-colic or gastrojejunal. Such fistulas are nearly always single,^{3, 7} although in 1 case there were two, with a jejunal ulcer in addition. The fistulas vary in diameter from a few millimeters to 6 cm²⁴ and are lined with a smooth mucous membrane, which usually shows no ulceration³ and in which the glands are regularly disposed. The colon is often constricted at the lesion, with resulting

partial obstruction and dilatation proximal to the fistula

An interesting feature of the lesion is that, as a rule, unless the fistula is very large the folds of jejunal mucosa act as a valve that prevents passage of gastric contents into the colon via the fistula^{2, 24} (Fig 2) but permits the regurgitation of feces and flatus into the jejunum and thence into the stomach. This explains the greater efficacy of barium enemas as compared to barium by mouth for visualizing these fistulas and further suggests why medications are ineffective in combating the diarrhea,

of the cases are reported by Atwater, Butt and Priestly.¹⁶

About half the patients complained of fecal-smelling eructation,^{16, 26} which was a more common finding than foul vomiting, since the passage of gas into the stomach from the colon takes place more readily than intestinal material and does not depend to the same degree on the fluidity of the large-bowel contents.³ Nausea and vomiting were present in 5 cases but both were not always present in the same patient. In the absence of intestinal obstruction, vomitus that is fecal in character is pathognomonic of a gastrocolic fistula.

Hematemesis occurred in 3 patients, 2 of whom also showed melena. A somewhat lower incidence was reported by Gray and Sharpe,²⁶ who found gastrointestinal hemorrhage in 30 per cent of gastrojejunal ulcers before a fistula had formed and 10 per cent after the fistula had become evident. Such bleeding is the chief cause of the varying degree of anemia found in over 50 per cent of the cases,¹⁶ although the generally debilitated state of the patients and their markedly altered nutrition undoubtedly also contribute to this finding. Gastric acidity studies are variable and of little diagnostic help, since bile and proximal jejunal contents inter-

mittently passing into the stomach neutralize the acidity to an unpredictable degree

Abdominal pain is an undependable symptom and is less related to meals, or relief by food and alkali, than the original ulcer discomfort is.¹⁹ Eusterman²⁸ states that in 85 per cent of the cases the pain is referred lower and farther to the left than that typically found with duodenal ulcer. Crampy lower abdominal discomfort accompanies partial large-bowel obstruction or irritation at the site of the lesion, whereas cessation of such pain and the onset of diarrhea suggest relief by the establishment of the fistula. There is little correlation between the location of pain and the finding of tenderness, and, in fact, the physical examination rarely re-

of surgical intervention without which the prognosis in this condition is progressive inanition and an early death from perforation, hemorrhage or intercurrent disease.^{3 8 29 30}

The first objective of treatment is to restore the patient to sufficiently good condition to withstand the formidable operative attack upon the fistula itself. This may be accomplished by medical measures alone if the condition has not persisted so long that emaciation is marked. The importance of intelligent use of blood transfusions, parenteral fluids and chemotherapeutic agents, both as a preliminary and as an adjunct to surgery, cannot be overstressed, and undoubtedly such measures are of prime significance in the marked lowering of the

*A duodenal ulcer was the original lesion in all the cases

†Date of operation for fistula

‡Excision of the fistula was of necessity part of the operation

veals any significant findings except for abdominal scars and evidence of emaciation. Occasionally an inflammatory mass can be felt,^{2 7 26} as in 2 of our cases.

Roentgenologic study of the intestinal tract by barium enema is the most helpful diagnostic procedure. Because of the valve-like action of the jejunal mucosa described above, a barium enema is more likely to demonstrate the fistula than a gastrointestinal series. This fact was emphasized in the report by Gray and Sharpe²⁶ of 49 cases confirmed by operation in which the fistula was revealed in only 13 of the 40 patients who had stomach x-ray films taken, whereas it was shown in all of the 25 studied by barium enema. In the present series, barium enema revealed the lesion in 5 of the 6 cases in which this procedure was carried out, whereas 4 of the 7 gastrointestinal series failed to reveal the fistula.

Enemas to which distinctive coloring matter has been added reveal the condition if the dye can be recovered by gastric lavage, and similar coloring material taken by mouth and found in the stool within a short period is suggestive of the diagnosis.

TREATMENT

There is no satisfactory medical treatment for gastrojejunal fistulas. Few diseases present a greater challenge to the proper timing and selection

of mortality rate in recent years. In certain cases, however, the effects of a long period of depletion may be so pronounced that supportive measures alone will be unavailing as adequate preoperative preparation unless the vicious circle of the self-perpetuating diarrhea is interrupted. Pfeiffer³⁰ was the first to emphasize the efficacy of a proximal shunt of the fecal stream to accomplish this end, and his advocacy in 1939 of an ascending colostomy as a preliminary procedure to corrective surgery stands as the most important single contribution to the treatment of gastrojejunal fistulas. With its adoption, the mortality has been reduced from levels as high as 63 per cent³¹ to below 5 per cent,³² and although many other types of side-tracking operations have been advanced by Marshall,¹ Dreosti,¹⁷ Lahey¹⁹ and others, none have proved superior to the originally advocated ascending colostomy in simply achieved effectiveness. Before the period of chemotherapy, peritonitis in these debilitated patients often followed even the simple procedure of colostomy or cecostomy, and 2 of the patients in this series on whom these procedures were carried out died in eight and fourteen days of peritonitis (Table 3).

After the initial treatment by appropriate medical or surgical measures, the problem of interrupting the fistulous tract must be met. This has been accomplished by many surgical procedures, including

simple division and closure of small fistulas, excision of the fistula and gastroenterostomy stoma with substitution of other varying types of gastroenterostomies with and without gastric resection, and *en-bloc* removal of the area of stomach, jejunum and colon involved in the fistulous process with re-establishment of the normal continuity of the intestinal tract. Progress and changes in the field of medicine, including the advent of chemotherapy, have led to certain modifications in the surgery of this condition but have not lessened the technical difficulties invariably presented by an inflammatory mass involving the upper and lower intestinal tract in a region distorted by the adhesions and altered anatomy resulting from the earlier operation.

Of the 7 patients in our series in whom a direct attack was made upon the fistula (1 of whom died of bronchopneumonia four days postoperatively), 4 had a resection of the fistula with restoration of intestinal continuity. In the remaining 3 gastric resection was carried out at the same time the fistula was surgically corrected. Although these patients all survived, there is a very considerable added hazard in this procedure.^{3, 21, 22}

The final phase in the treatment, unless a definitive surgical procedure has already been carried out, lies in dealing surgically with the patient's ulcer tendency, which has so insistently asserted itself by multiple manifestations in the past. With the patient's almost immediate improvement after correction of the fistula, the surgeon is often tempted to postpone further operation indefinitely. Such an attitude shows an understandable but misdirected consideration for the patient, for many reports^{4, 23} bear out the finding that if the intestinal continuity is restored a duodenal ulcer will again develop in from 20²⁴ to 40 per cent¹⁹ of the cases. This proneness to recurrence is well illustrated by the fact that in this series all 3 of the surviving patients in whom the normal anatomy of the intestinal tract was re-established exhibited new duodenal ulcers within three months to a year. All these patients were again operated upon after the recurrence of symptoms, and 1 of them died from peritonitis five days after a gastric exclusion operation.

Selection of a simple gastroenterostomy as the final definitive operation would merely serve to invite a repetition of the unfortunate train of events and would, in addition, show a disregard of the growing tendency to abandon such an operation for the treatment of this condition as pointed out above (Fig 1).

Gastric resection by one of the accepted technics has generally been used as the procedure of choice but is uniquely difficult and hazardous to perform because of adhesions and distortion due to the multiple antecedent operations in these patients. It was to avoid these technical intra-abdominal difficulties that consideration was given to trans-thoracic vagotomy as the definitive operation to

correct the ulcer diathesis in patients without pyloric obstruction.

In the following case this plan of treatment was successfully carried out. So far as we can determine this is the first report of a case in which such an operative policy was adopted, although before the definitive operation cited, the potential role of vagotomy in the treatment of gastrojejunal fistula was also suggested by Barber.³²

CASE REPORT

J C S (C V A H 1149), a 46-year-old single box maker, was well until the age of 34 years, when he underwent operation for a perforated peptic ulcer. Two years later posterior gastroenterostomy was done. He was then asymptomatic for 9 years, when pain recurred, this time in the left upper quadrant. Nine months later at the age of 46 he developed weakness, faintness and sweating, followed in 1 week by approximately nine bowel movements every night. His

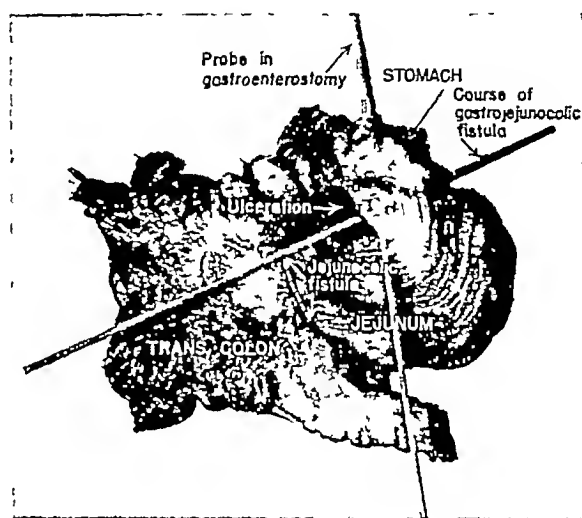

FIGURE 3 Specimen Showing a Fistula 2.5 cm in Diameter Opposite the Gastrojejunal Stoma

The resected portion of stomach is largely obscured by the opened jejunum

nocturnal diarrhea continued for 5 months, during which he lost 20 lb before his first admission to the Cushing Veterans Administration Hospital on December 16, 1946.

Physical examination revealed pallor, moderate emaciation and clubbing of the fingernails. The abdomen was protuberant, and an indefinite upper abdominal mass was palpable. Laboratory examinations were negative, except for a hemoglobin of 12.2 gm, a white-cell count of 14,050 and a total protein of 6.3 gm per 100 cc. Charcoal administered by mouth was passed by rectum in 2 hours and 10 minutes. A barium enema revealed a gastrojejunal fistula (Fig 2), although upper gastrointestinal x-ray studies characteristically failed to reveal the lesion.

Preoperatively, the patient was given 2 gm of sulfathalazine four times a day, and a total of 300,000 units of penicillin intramuscularly. The posterior gastroenterostomy and fistula were excised *en masse* (Fig 3), including a segment of the greater curvature of the stomach. The stomach was closed, and the continuity of the jejunum and of the colon was re-established by means of end-to-end anastomoses. The gastrojejunal fistula was 2.5 cm in diameter and opposite the gastrojejunal stoma, which was of similar size.

The postoperative course was uneventful. X-ray examination of the upper gastrointestinal tract 1 month after a leave from the hospital showed no evidence of ulcer. The fasting

FIGURE 4 Duodenal Ulcer Developing Three Months after Restoration of Intestinal Continuity Following Excision of a Gastrojejunal Colic Fistula

gastric content contained no free hydrochloric acid and 10% of total acidity. He was discharged and readmitted 1 month later because of a 2-week history of right-upper-quadrant

showed an ulcer crater, 1 by 2 cm, in the duodenal cap (Fig 4). A transthoracic vagus resection was done.

On the 18th postoperative day the patient had hematemesis, followed by melena. He continued to bleed for 5 days, during which he received 5½ pints of blood. Two months later there was no x-ray evidence of ulcer, and the insulin test (Fig 5) was consistent with complete vagus resection. One and a half years after the excision of the fistula and one year after the vagus resection he was asymptomatic and had well healed abdominal and thoracic scars. No free acid was secreted after insulin hypoglycemia. X-ray examination revealed no evidence of ulcer. The patient had gained back his 20 pounds in weight.

DISCUSSION

The case reported above re-emphasizes a number of fundamental considerations and introduces certain factors for further speculation. In the first place, the initial satisfactory response following extirpation of the fistula without a preliminary colostomy bears out the fact that, if the patient's condition is satisfactory, a first-stage operation with its inevitable soiling of the abdominal wall and need of eventual closure may be unnecessary. In case of doubt, however, such a procedure should be performed, but even this may be unavailing in avoiding a fatal outcome, as illustrated by Cases 4 and 6 in our series, if the patient's general condition is below a critical level.

A second fact illustrated by the case cited is that, if intestinal continuity is restored, the patient may develop an ulcer even though his progress is being followed by frequent visits, and thus he may be a less favorable candidate for a definitive surgical procedure than he would have been had such a final step been taken before discharge from the hospital.

Another interesting fact is the massive intestinal hemorrhage, presumably from the reactivated duodenal lesion that occurred eighteen days after vagotomy. After such an interval, it would be expected that, if the operation had been effective, healing of the ulcer would have progressed to a stage at which bleeding could not well have occurred. There can be little doubt from the findings of the insulin test, as well as the fact that both vagi were resected from 8 cm above the diaphragm to below the point at which they arborize, that the procedure had interrupted all impulses that might have reached the stomach over these nerves.

The possibility of performing vagotomy by the subdiaphragmatic route at the time the fistula is excised is naturally one that must be considered. The fact that it spares the patient further surgical treatment is an obvious advantage but one that seems to be more than outweighed by the possible contamination of the vulnerable subdiaphragmatic area by the potential soiling attendant on carrying out the anastomosis of the transverse colon. It is important to remember that with excision of the fistula and restoration of the intestinal tract there is bound to be a brief respite from ulcer symptoms during which the patient's general condition can

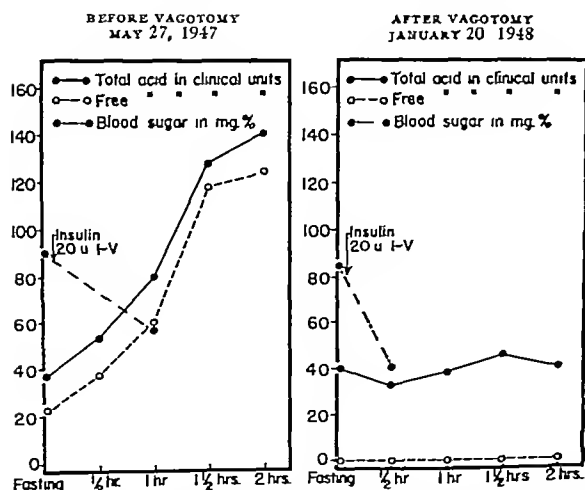

FIGURE 5 Insulin Tests before and after Vagotomy, Showing the Absence of Increased Acidity that Followed Insulin Hypoglycemia as an Indication of the Effectiveness of Vagus Resection

pain. He now had tenderness over the right upper quadrant and the fasting gastric content contained 51% of free hydrochloric acid and a total acidity of 75%. X-ray examination

still further improve before he is again subjected to the added risk of a definitive surgical operation. Furthermore, there are apt to be technical difficulties in satisfactorily exposing the esophageal hiatus by the subdiaphragmatic route because of adhesions from the previous operation and existing inflammatory reaction. These difficulties are obviated by a transthoracic approach to the final operation, and in such cases vagotomy can probably be carried out most effectively by such a route.³⁵

SUMMARY AND CONCLUSIONS

The findings in 9 cases of gastrojejunocolic fistula are presented, and the literature on the subject is reviewed.

The symptomatology is usually attributable to the secondary effects of diarrhea induced by the reflux of irritating large-bowel contents into the upper jejunum and stomach. Passage of gastric material into the colon through the fistula in the reverse direction is delayed, as a rule, by a valve-like action of the jejunal mucosa.

The treatment of gastrojejunocolic fistulas is surgical and consists of removing the fistula, restoring bowel continuity and correcting the ulcer diathesis.

Preparation of the patient for excision of the fistula should include the institution of an ascending colostomy as recommended by Pfeiffer as a preliminary procedure in all patients whose general condition is unsatisfactory.

The tendency in these patients to reactivate an ulcer after an excision of the fistula and restoration of intestinal continuity is so strong that unless corrective surgical measures have been carried out at the earlier operation they should be adopted before the patient is finally discharged from the hospital.

A case is cited for the first time in which, after excision of the fistula, transthoracic vagotomy was used as the definitive treatment of the ulcer diathesis. This patient was asymptomatic a year after the vagus resection.

The postoperative course was uneventful. X-ray examination of the upper gastrointestinal tract 1 month after a leave from the hospital showed no evidence of ulcer. The fasting

FIGURE 4 Duodenal Ulcer Developing Three Months after Restoration of Intestinal Continuity Following Excision of a Gastrojejunocolic Fistula

gastric content contained no free hydrochloric acid and 10° of total acidity. He was discharged and readmitted 1 month later because of a 2-week history of right-upper-quadrant

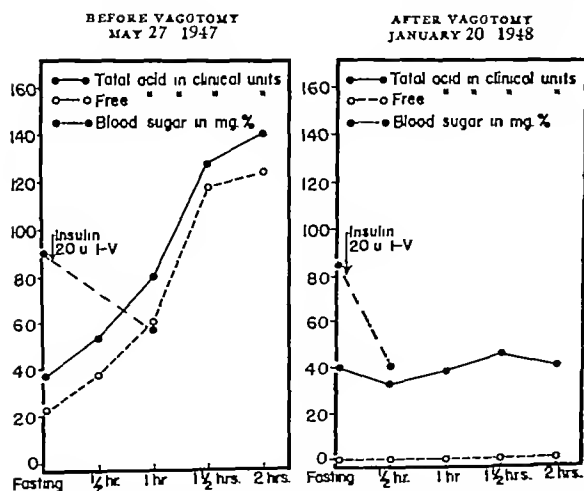

FIGURE 5 Insulin Tests before and after Vagotomy, Showing the Absence of Increased Acidity that Followed Insulin Hypoglycemia as an Indication of the Effectiveness of Vagus Resection

pain. He now had tenderness over the right upper quadrant and the fasting gastric content contained 51° of free hydrochloric acid and a total acidity of 75°. X-ray examination

showed an ulcer crater, 1 by 2 cm, in the duodenal cap (Fig 4). A transthoracic vagus resection was done.

On the 18th postoperative day the patient had hematemesis, followed by melena. He continued to bleed for 5 days, during which he received 5½ pints of blood. Two months later there was no x-ray evidence of ulcer, and the insulin test (Fig 5) was consistent with complete vagus resection. One and a half years after the excision of the fistula and one year after the vagus resection he was asymptomatic and had well healed abdominal and thoracic scars. No free acid was secreted after insulin hypoglycemia. X-ray examination revealed no evidence of ulcer. The patient had gained back his 20 pounds in weight.

DISCUSSION

The case reported above re-emphasizes a number of fundamental considerations and introduces certain factors for further speculation. In the first place, the initial satisfactory response following extirpation of the fistula without a preliminary colostomy bears out the fact that, if the patient's condition is satisfactory, a first-stage operation with its inevitable soiling of the abdominal wall and need of eventual closure may be unnecessary. In case of doubt, however, such a procedure should be performed, but even this may be unavailing in avoiding a fatal outcome, as illustrated by Cases 4 and 6 in our series, if the patient's general condition is below a critical level.

A second fact illustrated by the case cited is that, if intestinal continuity is restored, the patient may develop an ulcer even though his progress is being followed by frequent visits, and thus he may be a less favorable candidate for a definitive surgical procedure than he would have been had such a final step been taken before discharge from the hospital.

Another interesting fact is the massive intestinal hemorrhage, presumably from the reactivated duodenal lesion that occurred eighteen days after vagotomy. After such an interval, it would be expected that, if the operation had been effective, healing of the ulcer would have progressed to a stage at which bleeding could not well have occurred. There can be little doubt from the findings of the insulin test, as well as the fact that both vagi were resected from 8 cm above the diaphragm to below the point at which they arborize, that the procedure had interrupted all impulses that might have reached the stomach over these nerves.

The possibility of performing vagotomy by the subdiaphragmatic route at the time the fistula is excised is naturally one that must be considered. The fact that it spares the patient further surgical treatment is an obvious advantage but one that seems to be more than outweighed by the possible contamination of the vulnerable subdiaphragmatic area by the potential soiling attendant on carrying out the anastomosis of the transverse colon. It is important to remember that with excision of the fistula and restoration of the intestinal tract there is bound to be a brief respite from ulcer symptoms during which the patient's general condition can

exacerbation, and the cephalin-cholesterol flocculation was +++

CASE 2 M G, a 20-year-old student nurse, was admitted to the hospital on November 24, 1947, complaining of vague abdominal distress consisting of "fullness" and aching in the upper abdomen associated with frequent eructation of 6 days' duration. This was followed by nausea without vomiting and anorexia so that she had eaten little or nothing for 24 to 36 hours prior to admission, moreover, the mere sight of food nauseated her. On each of three successive days, prior to admission, she had noticed "light, almost clay-colored stools" — no change in the color of the urine had been noted. In addition to these findings she had been listless and depressed. There was no history of plasma or blood infusion or inoculations within 6 months or exposure to chemicals. She was,

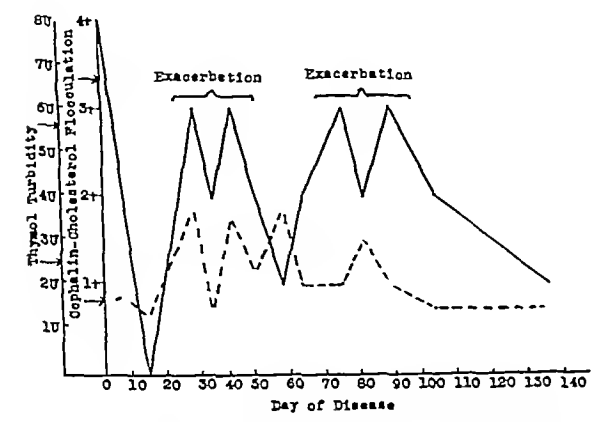

FIGURE 2 Relation of Liver Function to Clinical Course in Case 2

however, quartered in the same building as the patient in Case 1. The family and past histories and a system review were all noncontributory to the present illness. Physical examination revealed a well developed, well nourished patient, who was not acutely ill. Examination showed normal findings except for tenderness without spasm in the right upper quadrant. The liver and spleen were not palpable, but there was tenderness to jarring over the right lower thoracic cage. The temperature was 99°F, the pulse 80, and the blood pressure 110/80. On November 24 the white-cell count was 7500, with 32 per cent neutrophils and 64 per cent lymphocytes. The erythrocyte sedimentation rate was 21 mm per hour. The urine was negative for bile, and urobilinogen was present in a dilution of 1:8. The icteric index was 11 units. The prothrombin time was 78 per cent of normal. The cephalin-cholesterol flocculation was + + + +, and the thymol turbidity was 1.6 units. The heterophil-antibody agglutination was negative, as were a gall-bladder and a gastrointestinal series. Subsequent liver-function tests are recorded in Figure 2. The treatment was the same as that in Case 1. Within a few days of admission the right-upper-quadrant distress became more marked and more sharply localized, and at the same time the patient complained of aching in the left upper quadrant. Examination revealed a palpable, tender spleen. There was a 6-lb weight loss in 2 weeks. On December 8 she felt much better — that is, the right-upper-quadrant tenderness had markedly diminished, and the spleen was no longer palpable. From this time on gradual improvement was noted, and she was discharged on December 20 to the care of her parents, who had been instructed regarding convalescence. The patient was readmitted 8 days after discharge, complaining of recurrence of fatigue, anorexia, nausea without vomiting and distress in both upper quadrants.

Physical examination was essentially the same as on the previous admission, showing tenderness without spasm to palpation in both upper quadrants associated with tenderness to jarring over the right lower and left lower thoracic cage. The temperature was 99.4°F. The only significant laboratory findings were a cephalin-cholesterol flocculation of + + + and a thymol turbidity test of 3.7 units on the day of discharge, on the day of readmission these values were, respectively, + + and 1.3 units. Subsequent liver-function tests are recorded in Figure 2. Cerebrospinal-fluid examination, which was done for reasons explained below, showed a protein of 45 mg per 100 cc. but no cells. The treatment was the same as that on the previous admission. There were three well defined exacerbations, manifested by nausea, anorexia, general malaise, headache and increased distress in the upper quadrants, with increased tenderness to palpation. The spleen was occasionally palpable, but the liver was not felt. The exacerbations were rather accurately reflected by the liver-function tests. On January 17, 1948, because of persistent headache, a lumbar puncture was done to rule out a complicating encephalitis and the findings were as listed above. On January 25 the patient began to feel better as manifested by amelioration of symptoms and abdominal tenderness. She was discharged but has been followed as an outpatient, and her course has been one of slow gradual improvement. She was back on duty 4½ months after the onset of illness.

CASE 3 N S, a 21-year-old student nurse, was admitted to the hospital on November 17, 1947, complaining of nausea and lack of appetite of 5 days' duration. She had not been well for 2 or 3 months before admission because of fatigue and weakness, but repeated examinations at sick call had been negative. Four or five days prior to admission, however, a

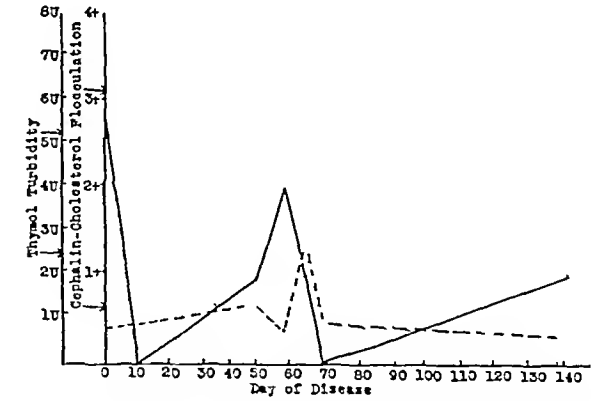

FIGURE 3 Relation of Liver Function to Clinical Course in Case 3

decided change had occurred in the form of intense nausea without vomiting, general malaise, anorexia with an aversion to food and marked fatigue. There was no history of plasma or blood infusion, inoculations or exposure to chemicals within the last 6 months. The patient, being a student nurse, was quartered in the same building as the patients in Cases 1 and 2. The family and past histories and a system review were noncontributory to the present illness. Physical examination revealed a well developed, well nourished patient, who was not acutely ill but appeared rather listless. Complete examination disclosed normal findings except for tenderness to palpation in a sharply localized area in the right upper quadrant. There was no associated muscle spasm, but there was tenderness to jarring over the right lower thoracic cage. The liver and spleen were not palpable, and there was no lymphadenopathy. The temperature was 99.2°F, the pulse 80, and the blood pressure 110/72.

HEPATITIS WITHOUT JAUNDICE AND WITHOUT HEPATOMEGALY

T. J. DOMENICI, M.D.*

MALDEN, MASSACHUSETTS

FOUR cases of hepatitis without jaundice and without hepatomegaly constitute the material of this report. Hepatitis without jaundice has been variously described as a "mild disease"¹ and "mild non-icteric form of hepatitis,"² running a course of six to eight weeks. A review of the literature reveals that an enlarged and tender liver is an essential finding in virus hepatitis and in the hepatitis seen in infectious mononucleosis. The cases presented below were severe illnesses running a four to six months' course. The liver was not enlarged, but instead a sharply circumscribed area of localized tenderness in the right upper quadrant was elicited in all cases. The protracted course, marked by exacerbations and remissions, was associated with marked psychologic turmoil. Whether this fact was an integral part of the disease or a consequence of chronic illness remains open to question. At any rate, irrespective of source, the management of this aspect of the illness proved to be most difficult and is worthy of emphasis.

CASE REPORTS

CASE 1 D.G., a 20-year-old student nurse, was first admitted to the hospital on November 10, 1947, complaining of aching pain in the right upper abdomen, nausea at sight of food, loss of appetite and vomiting of 4 days' duration. She

FIGURE 1 Relation of Liver Function to Clinical Course in Case 1

was seen, as an outpatient, at the onset of illness, on the Surgical Service and after twenty-four hours it was decided that surgical treatment was not indicated. The white-cell count at that time was 13,400, with 82 per cent neutrophils.

The patient had not received plasma, blood or inoculations within the 6 months prior to admission. There was no known exposure to chemicals or to patients with virus hepatitis.

*Resident in medicine, Malden Hospital.

The family and past histories and a system review were all noncontributory to the present illness.

Physical examination revealed a well developed, well nourished patient who was not acutely ill. Complete examination revealed normal findings except for a sharply circumscribed area of localized tenderness without spasm in the right upper quadrant just lateral to the midline. This was associated with tenderness to jarring over the right lower thoracic cage. The liver and spleen were not palpable, and there was no lymphadenopathy.

The temperature was 99°F, the pulse 80, and the blood pressure 126/84.

On November 11 the white-cell count was 8000, with 33 per cent neutrophils and 40 per cent lymphocytes. The erythrocyte sedimentation rate was 14 mm per hour. The urine was negative for bile, and urobilinogen was present in a dilution of 1:16 (normal 1:8). The icteric index was 5 units, the prothrombin time was 68 per cent of normal and remained above this value for the duration of the hospital stay. Urinary urobilinogen varied from 1:4 to 1:16, and the white-cell count from 6000 to 8000, with 35-40 per cent lymphocytes. The heterophil-antibody agglutination and gall-bladder and gastrointestinal series were negative. Erythrocyte sedimentation remained within normal limits. Repeat cephalin-cholesterol flocculation and the thymol turbidity tests during both periods of hospitalization are shown in Figure 1.

Glucose (5 per cent) in physiologic saline solution and protein hydrolysate were given intravenously in the first 60 to 72 hours because of almost complete anorexia and vomiting. Subsequent treatment consisted of absolute bed rest, a diet consisting of 250 gm of carbohydrate, 100 gm of protein and 80 gm of fat, multi-vitamins, components of the vitamin B complex and vitamin K in therapeutic doses daily and supplementary high-protein drinks. At first methionine and choline (1 gm each, three times daily) were given, but they were discontinued within 3 to 4 weeks, partly because of inability to disguise the amino acid in a palatable drink.

The appetite remained poor, and there was a 15-lb weight loss in 1 month. The clinical course was characterized by exacerbations manifested by anorexia, nausea, general malaise and increased tenderness in the right upper quadrant. In some instances this was reflected by a rise in the cephalin-cholesterol flocculation and thymol turbidity tests. After 6 weeks it seemed that the patient had reached a *status quo* and she was discharged on December 24 to the care of her family, who had received careful and detailed instructions regarding convalescence.

The patient was readmitted on December 30 complaining of severe anorexia, continuing weight loss, overwhelming and seemingly progressive fatigue and varying right-upper quadrant distress.

Physical examination revealed evidence of further weight loss to 110 lb, and the positive findings consisted of tenderness to palpation in the right upper quadrant in exactly the same area described in the previous physical examination. This was again associated with tenderness to jarring over the right lower thoracic cage.

The cephalin-cholesterol flocculation was ++, though the thymol turbidity was within normal range, being 13 units. There were no other significant findings.

The therapeutic measures employed were essentially the same as those for the previous hospitalization.

The patient was again discharged on February 19, 1948, when it seemed that she had started to improve—that is, her appetite was better, the right-upper-quadrant tenderness was minimal, and there had been a slow weight gain of 2 lb. Approximately 7 to 10 days after discharge she suffered another exacerbation. She returned for a trial on duty on April 23, approximately 5½ months after the onset of the illness. However, after 1 month on duty, she suffered another

early symptom and may be severe enough to result in significant weight loss. Appetite and weight loss are only painstakingly regained. The long, rather than short, course makes subsequent chronic liver disease, as mentioned by Chaikin and Chlenoff,⁷ an eminent possibility.

The long course of the illness was attended by marked psychologic disturbance, which, to say the least, complicates the management and treatment. The constant urging and prodding to "eat more" soon engenders in the patient an antagonism for food manifested by a mildly belligerent insistence that "I'm eating as much as I can." The weight lost was only slowly regained, if at all. With prolonged bed rest time soon weighs heavy, particularly in young vigorous adults. Attempts to counteract this by means of occupational therapy were, on the whole, only partially successful.

The cephalin-cholesterol flocculation as mentioned by others⁸⁻¹¹ proved to be a sensitive and reliable test and seemed to bear a relation to the clinical course. The thymol turbidity did not reach the high values reported elsewhere but did show a delayed rise occurring after clinical manifestations of activity.¹²⁻¹⁴

The negative heterophil-antibody agglutination, the absence of lymphadenopathy and the absence of the "atypical" lymphocyte of infectious mononucleosis seem to rule out that disease. The negative history regarding plasma or blood infusions and inoculations, for six months prior to onset of illness, eliminates homologous serum jaundice as a possibility.

SUMMARY

Four cases of hepatitis without jaundice and without hepatomegaly are presented. The finding

of a sharply circumscribed area of localized tenderness in the right upper quadrant was elicited in all cases and appeared to be as significant as a palpable liver.

The course of the disease was long and severe and resulted in the appearance of functional factors that proved difficult to manage.

The cephalin-cholesterol flocculation seemed to be the most sensitive and reliable index of both the liver function and the clinical course.

On November 18 the white-cell count was 5400, with 59 per cent neutrophils and 31 per cent lymphocytes. The sedimentation rate was 17 mm per hour. The icteric index was 6 units. The prothrombin time was 67 per cent of normal. The urine was negative for bile, and urobilinogen was present in a dilution of 1:8. The cephalin-cholesterol flocculation was +++, and the thymol turbidity was 0.8 units. Repeat performances of these tests at regular intervals yielded normal values, and subsequent liver-function tests are recorded in Figure 3.

Except for minor variations, therapy was the same as that described for Cases 1 and 2.

This patient's illness was a comparatively mild one, though for the first 10 days, anorexia and right-upper-quadrant distress were quite marked. The discomfort gradually subsided, however, and the appetite returned slowly after a minimal loss of weight. The patient was discharged to her home for further convalescence.

She was readmitted 3 weeks after discharge, with a history of a bout of diarrhea beginning 2 days after discharge and consisting of 4 or 5 loose, nonbloody stools daily, without cramps, that lasted for 5 days. Subsequently, she became anorexic, and right-upper-quadrant distress returned.

Physical examination was negative except for a temperature of 99.2°F, and minimal tenderness to palpation in the right upper quadrant.

Laboratory findings of significance were a cephalin-cholesterol flocculation of +, a thymol turbidity of 1.4 units and a prothrombin time 66 per cent of normal. Gall-bladder and gastrointestinal series were negative. Heterophil-antibody agglutination was also negative. The prothrombin time after 10 days of vitamin K therapy was 88 per cent of normal.

The same treatment as on the previous admission was given.

Again, this patient's illness was comparatively mild, though prolonged. Her appetite gradually returned, and right-upper-quadrant tenderness remained minimal. From then on improvement was gradual and without exacerbations. She was discharged on January 27, and she returned to duty 4 months after the onset of the illness.

CASE 4 R. K., a 29-year-old graduate nurse, was admitted to the hospital on November 26, 1947, complaining of loss of appetite, nausea, general malaise and lassitude of 3 days' duration. This patient was charge nurse on the pediatric

ized area of tenderness in the right upper quadrant associated with tenderness to jarring over the right lower thoracic cage. The liver and spleen were not palpable, and there was no lymphadenopathy.

The temperature was 99.6°F, the pulse 74, and the blood pressure 100/60.

On November 26 the white-cell count was 6500, with 63 per cent neutrophils and 32 per cent lymphocytes. The sedimentation rate was 21 mm per hour. The icteric index was 5 units, the prothrombin time was 80 per cent of normal. The urine was negative for bile, and urobilinogen was present in a dilution of 1:4 to 1:8. Cephalin-cholesterol flocculation was +++, and the thymol turbidity was 2.1 units. Periodic performance of the above tests were all normal, and subsequent liver-function tests are recorded in Figure 4.

The treatment was the same as that for the 3 previous cases.

Clinically, there was marked anorexia, nausea, right-upper-quadrant tenderness and a 12-lb weight loss in 2 weeks. After approximately 3 weeks the patient began to improve—that is, the appetite returned, right-upper-quadrant tenderness diminished, and there was a slow gain in weight. She was discharged to her home on December 24. Blood taken on the day of discharge, however, revealed a +++ cephalin-cholesterol flocculation and 2.6-unit thymol turbidity. She was followed at home, and for the first 6 weeks there she did not fare well: the appetite was poor, nausea recurred, tenderness in the right upper quadrant returned and her weight dropped to 90 lb (the weight at the onset of the illness having been 100 lb). Within a week there was decided improvement, which has been progressive except for one minor setback. She has not, however, regained her lost weight and at present she weighs 92 lb. At this writing, 3 months after the onset of the illness, she is not yet ready to work.

EPIDEMIOLOGY

It is perhaps fair to assume that Case 1 was the source of infection for the remaining 3. The source of infection for the first case, however, was not known. The history, as elicited, rules out plasma or blood infusions, chemicals and inoculations. All 4 patients lived in the same building, and the fact that only 3, out of about 50 persons, succumbed to exposure to the first case is perhaps best explained according to Newman⁴—that is, the liver is phasic in activity, and hence susceptibility to infection is variable, thus the phase of susceptibility at time of exposure determines whether or not a person will succumb to infection.

DISCUSSION

The presence of an enlarged liver is mentioned in all articles on hepatitis without jaundice.^{1,2,5,6} As mentioned above the liver was not palpable in this group of cases. There was, however, in each case a sharply localized area of tenderness in the right upper quadrant toward the midline, and this was associated with tenderness to jarring over the right lower thoracic cage. This finding, in my experience, was as significant as an enlarged liver and served as a reliable index to the clinical state.

The clinical course is marked by exacerbations and remissions characterized by varying degrees of anorexia, fluctuating intensity of right-upper-quadrant tenderness and varying degrees of generalized malaise. Some exacerbations are accompanied by a rise in temperature. Anorexia is a constant and

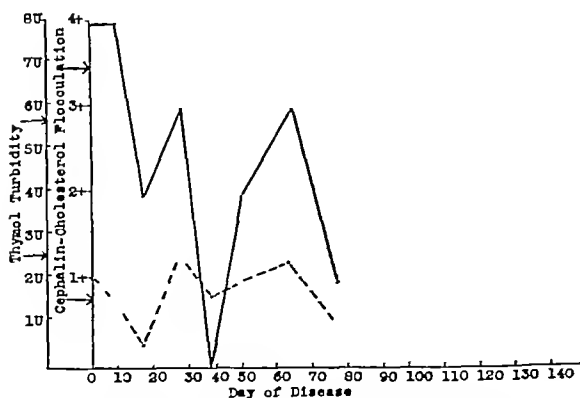

FIGURE 4 Relation of Liver Function to Clinical Course in Case 4

floor where 2 of the other 3 patients had worked, and she had been active in the care of these patients.

There was no history of plasma or blood infusion, inoculations or exposure to chemicals within the last 6 months.

The family and past histories and a system review were noncontributory to the present illness.

Physical examination revealed a well developed, well nourished woman who was not acutely ill. Complete examination disclosed normal findings except for a definite, sharply local-

was dazed but not made unconscious. Later, he had some fever and vomited. He was fairly well until twenty-four hours later, when he became first drowsy and then unconscious, with paralysis of the right arm, leg and face. The right pupil was larger than the left, but reacted to light, there was incontinence of urine and feces, and pressure on a contusion behind the left ear caused crying. Nine hours later he was partially conscious and was regaining the use of the paralyzed muscles, so that operation was delayed. Six days after the accident he was completely well, except for a complicating sore throat, which was considered to be a coincidence. The third report, also by Walton,² concerned a three-and-a-half-year-old girl who was thrown to the floor from a small swing and struck her head. She was dazed, and later vomited. On the following day she had paralysis of the left arm, and exploration of the head was advised. Overcrowding of the hospital caused a delay of twelve hours, by which time she seemed much better and was beginning to use the left hand, so that no operation was done. Her convalescence was rapid, and she made a quick and complete recovery, being entirely well when seen two years later. Walton regards these patients as having had subarachnoid serous exudation and says

That a more or less diffuse oedema, whether involving the subarachnoid cavity or the brain itself, or both, and whether accompanied or not by marked laceration, may play a part in prolonging the general symptoms of concussion, seems a not improbable supposition, it is not, however, of this class of cases that I would speak at length, but rather of those cases in which a local paralysis of more or less temporary nature accompanies such general symptoms, the pathology being here, I apprehend, a local accumulation of fluid under the arachnoid resulting from rapid exudation at the point of most marked bruising, whether the result of direct violence or of contrecoup. For the unilateral paralysis there seems absolutely no plausible explanation, except the pressure of the fluid, and the relief of paralysis was apparently due to relief of this pressure. This lesion is to be particularly borne in mind in the case of children and young adults, and perhaps in alcoholic patients. In elderly patients the same set of symptoms points more decidedly toward hemorrhage.

Cushing³ discusses the physiologic effects of acute compression and states

We must continually bear in mind the difference between a local and a general increase in tension. Inasmuch as the pressure effects of a local process are greater in its immediate neighborhood than at a distance, and inasmuch also as there is considerable pressure discontinuity between the three intracranial compartments, owing to the fairly rigid partitions formed by the falx and tentorium cerebelli, a local pressure, let us say over one hemisphere, may exceed the local arterial pressure and lead to a local anemia sufficient to throw the adjoining parts of the brain out of function without seriously affecting the other hemisphere or the subtentorial structures, of which the medulla is of prime importance.

And in considering extradural and subdural hemorrhage, he says "Confusion may arise in certain cases, owing to the fact that acute, traumatic cerebral edema may closely simulate the general pressure phenomena which accompany actual extravasations of blood."⁴

Current authorities on head injuries recognize the existence of states imitating extradural bleeding, but do not lay great stress upon them. Munro^{5, 6} remarks

In children, hemiplegia and convulsions commonly occur in uncomplicated cerebral oedema. There appears to be a type of malignant and sometimes strictly localized oedema of the brain that will present expansive characteristics. I have usually seen it develop as a postoperative complication.

Rowbotham⁷ believes that interval hemiplegias may be caused by edema, among other conditions. Brock⁸ writes "For rare instances of so-called malignant edema which develop rapidly and do not respond to ordinary methods of dehydration and repeated lumbar puncture, exploratory trephine will have to be resorted to, to rule out meningeal hemorrhage." Gross and Ehrlich⁹ deny the existence of a process such as that assumed above and say

Focal edema of the brain with the development of localizing signs and symptoms which simulate a middle meningeal hemorrhage, has been postulated by numerous observers. This has been used to justify exploration when middle meningeal hemorrhage has been sought and not found, and yet recovery has ensued. It is possible that an extradural clot may be confined over the occipital or occipito-parietal area, more rarely its situation may be far anterior. The improvement following negative exploration can probably be attributed to the decompressive effects concomitant with opening of the dura mater. This serves to prevent fatal cerebral compression. With the tiding over of the critical period, life is sustained, and as the epidural clot slowly reabsorbs, recovery takes place.

At the Rhode Island Hospital, during the past five years, we have treated a total of 8 patients on whom we made the diagnosis of acute focal edema of the brain. The ages varied from ten months to eleven years, we have seen no clear-cut case in an adult. In the same period we have had over 500 children with head injuries, so that the incidence in our experience is low, being well under 2 per cent. Seven of these children were boys. In most cases the child fell and struck his head on the floor or the ground. Linear fracture of the vault, without depression, was present in 3 cases, in 1 of which there was an additional fracture of the maxilla. There was initial unconsciousness in 3 patients. The interval between the injury and the onset of focal signs varied from fifteen minutes to six hours. The focal signs included one-sided reflex changes indicating cortical involvement, Jacksonian convulsive movements and in 1 patient a combination of Jacksonian and generalized convulsions, and one-sided paralyses of varying degrees. Traumatic shock was present in only 2 patients.

It is our practice not to do a lumbar puncture in the presence of shock or when acute extradural or subdural bleeding is suspected, for fear of lessening intracranial pressure and thus increasing bleeding, for these reasons, the cerebrospinal-fluid findings during the active phase of this condition are not available. Punctures done during

ACUTE FOCAL EDEMA OF THE BRAIN IN CHILDREN WITH HEAD INJURIES*

WILFRED PICKLES, M D †

PROVIDENCE, RHODE ISLAND

ON MARCH 18, 1943, the very active two-and-a-half-year-old son of a surgical colleague fell from his high chair with such force that his head bounced on the floor. He seemed dazed for a moment or two but had no definite period of unconsciousness. He cried loudly for a few minutes, as one might expect, but soon seemed to forget all about the fall and was apparently as well as ever. He ate his supper with a good appetite, and was put to bed. Two hours later he began to vomit, he was very pale and his skin was moist and cold, and he was very drowsy, with occasional convulsive twitchings of the right arm and leg. His mother, who is a nurse, believed that he had a severe head injury, so he was taken at once to the hospital. On arrival he was found to be in shock, with poor peripheral circulation and a low temperature, he was semicomatose and had greatly depressed reflexes and motor power of the right arm and leg, and he was admitted with the diagnosis of extradural hemorrhage as a dangerously ill patient. Treatment for traumatic shock was started, and preparations for a cranial exploration were got under way. At about the time when these were completed his condition began to improve, the signs of shock lessened, the semi-coma lightened, the reflexes on the right side became more active, and he moved his arm and leg with more power. In four hours he was so much better that it was evident that exploration would not be needed, and by the next morning, some sixteen hours after the injury, he was fully conscious and happy, with no evident neurologic abnormality. X-ray films of the skull showed no fracture. About a week later a mild bronchopneumonia, which responded well to treatment with sulfadiazine, developed. Recovery was otherwise without incident, and he was discharged at the end of three weeks. He has been examined often since then, and has at no time shown any remaining evidence of the injury.

The course of events in this case left me at a loss for an accurate explanation, when the need for proper diagnosis arose. At my first examination, the child presented an almost classic picture of a patient with compression of the brain from an extradural hemorrhage, but it did not seem reasonable to hold to this diagnosis in view of the rapid and complete clearing up of signs and symptoms without operative relief. It was evident that there had not been time for the absorption of an extradural hematoma or of a subdural collection of blood causing the same sort of local pressure. The possibility

that the sudden relief of symptoms was due to the spreading into a thin layer of a previously localized blood mass in either the extradural or the subdural space was considered, but this seemed to be quite unlikely without some residual effect. Local contusion of the cortex, with its associated actual tissue damage, could have accounted for the signs of motor and reflex involvement, but here again, the recovery came too soon. An acute focal edema of the brain, bringing about the same sort of local ischemia as that caused by an extradural hematoma, could have caused the conditions present when the boy was admitted, it could have been resolved quickly enough to allow the speed of improvement shown, and it could quite properly have been expected to clear up without permanent brain damage. As there seemed to be no better explanation, this was accepted as a working diagnosis, and further examples were sought for, in the hope of proving or disproving the actual existence of such a focal edema.

This occurrence of clinical findings strongly suggesting extradural bleeding but apparently due to some other condition has been noted in the writings of others interested in this subject. The only actual case reports that I have found so far were published by Boston observers some fifty years ago. The first one, by Walton and Brooks,¹ gives the history of a young woman who was thrown from a horse, struck her head violently against a rail, and developed signs suggesting middle meningeal hemorrhage. At operation, neither extradural nor subdural bleeding was found, but on opening the dura the surgeon released about half an ounce of clear serum, and believed that the brain was edematous but otherwise normal. The patient improved slightly for a time, but then became worse and died. Post-mortem examination showed a few small areas of deep hemorrhage, none of which explained the unilateral paralysis, and the authors concluded that this had been caused by local edema. In the course of their discussion they said

It is not uncommon in children to find local paralysis following blows upon the head, closely simulating the results of hemorrhage, but completely disappearing in the course of a week or two, a fact which has to be borne in mind in making the diagnosis of middle meningeal hemorrhage in early life. The case here reported, together with others which have been called to our attention, would seem to indicate that similar conditions may obtain in adult life. Whether this pathology is accepted or not, the practical bearing of such cases upon our experience is* to throw a certain weight in favor of conservatism in doubtful cases, though by no means lessening the demand for operation in the typical case.

†Surgeon in-chief, Department of Neurosurgery, Rhode Island Hospital.

The second patient, reported by Walton,² was a six-year-old boy who was struck by a bicycle and

was dazed but not made unconscious. Later, he had some fever and vomited. He was fairly well until twenty-four hours later, when he became first drowsy and then unconscious, with paralysis of the right arm, leg and face. The right pupil was larger than the left, but reacted to light, there was incontinence of urine and feces, and pressure on a contusion behind the left ear caused crying. Nine hours later he was partially conscious and was regaining the use of the paralyzed muscles, so that operation was delayed. Six days after the accident he was completely well, except for a complicating sore throat, which was considered to be a coincidence. The third report, also by Walton,² concerned a three-and-a-half-year-old girl who was thrown to the floor from a small swing and struck her head. She was dazed, and later vomited. On the following day she had paralysis of the left arm, and exploration of the head was advised. Overcrowding of the hospital caused a delay of twelve hours, by which time she seemed much better and was beginning to use the left hand, so that no operation was done. Her convalescence was rapid, and she made a quick and complete recovery, being entirely well when seen two years later. Walton regards these patients as having had subarachnoid serous exudation and says

That a more or less diffuse oedema, whether involving the subarachnoid cavity or the brain itself, or both, and whether accompanied or not by marked laceration, may play a part in prolonging the general symptoms of concussion, seems a not improbable supposition, it is not, however, of this class of cases that I would speak at length, but rather of those cases in which a local paralysis of more or less temporary nature accompanies such general symptoms, the pathology being here, I apprehend, a local accumulation of fluid under the arachnoid resulting from rapid exudation at the point of most marked bruising, whether the result of direct violence or of contrecoup. For the unilateral paralysis there seems absolutely no plausible explanation, except the pressure of the fluid, and the relief of paralysis was apparently due to relief of this pressure. This lesion is to be particularly borne in mind in the case of children and young adults, and perhaps in alcoholic patients. In elderly patients the same set of symptoms points more decidedly toward hemorrhage.

Cushing³ discusses the physiologic effects of acute compression and states

We must continually bear in mind the difference between a local and a general increase in tension. Inasmuch as the pressure effects of a local process are greater in its immediate neighborhood than at a distance, and inasmuch also as there is considerable pressure discontinuity between the three intracranial compartments, owing to the fairly rigid partitions formed by the falx and tentorium cerebelli, a local pressure, let us say over one hemisphere, may exceed the local arterial pressure and lead to a local anemia sufficient to throw the adjoining parts of the brain out of function without seriously affecting the other hemisphere or the subtentorial structures, of which the medulla is of prime importance.

And in considering extradural and subdural hemorrhage, he says "Confusion may arise in certain cases, owing to the fact that acute, traumatic cerebral edema may closely simulate the general pressure phenomena which accompany actual extravasations of blood."

Current authorities on head injuries recognize the existence of states imitating extradural bleeding, but do not lay great stress upon them. Munro^{5, 6} remarks

In children, hemiplegia and convulsions commonly occur in uncomplicated cerebral oedema. There appears to be a type of malignant and sometimes strictly localized oedema of the brain that will present expansile characteristics. I have usually seen it develop as a postoperative complication.

Rowbotham⁷ believes that interval hemiplegias may be caused by edema, among other conditions. Brock⁸ writes "For rare instances of so-called malignant edema which develop rapidly and do not respond to ordinary methods of dehydration and repeated lumbar puncture, exploratory trephine will have to be resorted to, to rule out meningeal hemorrhage." Gross and Ehrlich⁹ deny the existence of a process such as that assumed above and say

Focal edema of the brain with the development of localizing signs and symptoms which simulate a middle meningeal hemorrhage, has been postulated by numerous observers. This has been used to justify exploration when middle meningeal hemorrhage has been sought and not found, and yet recovery has ensued. It is possible that an extradural clot may be confined over the occipital or occipito-parietal area, more rarely its situation may be far anterior. The improvement following negative exploration can probably be attributed to the decompressive effects concomitant with opening of the dura mater. This serves to prevent fatal cerebral compression. With the tiding over of the critical period, life is sustained, and as the epidural clot slowly reabsorbs, recovery takes place.

At the Rhode Island Hospital, during the past five years, we have treated a total of 8 patients on whom we made the diagnosis of acute focal edema of the brain. The ages varied from ten months to eleven years, we have seen no clear-cut case in an adult. In the same period we have had over 500 children with head injuries, so that the incidence in our experience is low, being well under 2 per cent. Seven of these children were boys. In most cases the child fell and struck his head on the floor or the ground. Linear fracture of the vault, without depression, was present in 3 cases, in 1 of which there was an additional fracture of the maxilla. There was initial unconsciousness in 3 patients. The interval between the injury and the onset of focal signs varied from fifteen minutes to six hours. The focal signs included one-sided reflex changes indicating cortical involvement, Jacksonian convulsive movements and in 1 patient a combination of Jacksonian and generalized convulsions, and one-sided paralyses of varying degrees. Traumatic shock was present in only 2 patients.

It is our practice not to do a lumbar puncture in the presence of shock or when acute extradural or subdural bleeding is suspected, for fear of lessening intracranial pressure and thus increasing bleeding, for these reasons, the cerebrospinal-fluid findings during the active phase of this condition are not available. Punctures done during

or soon after the subsidence of the acute symptoms, however, have shown normal pressures, normal protein levels and the absence of red blood cells in most cases, in 2 patients, the fluid has shown a few red cells, and in 1 it has shown a slight rise in the amount of protein relative to the age, being 36 mg per 100 cc in a boy of eleven years. The time needed for the complete disappearance of clinical evidence of the condition has varied from three to twenty-four hours.

We had thus gone along for five years, making this tentative diagnosis as a logical necessity but without actual proof of its existence, until May 1, 1948, when a four-year-old girl was admitted to the hospital. An hour earlier, she had been knocked down by a bicycle and had struck her head on the sidewalk. She became unconscious at once and was carried into the house, where she regained consciousness in a few minutes and vomited. Fifteen minutes later she again lapsed into unconsciousness and began to have convulsive movements of both arms and legs, the left arm and leg being definitely more involved than the right. On admission she was completely comatose, with no apparent response to any stimulus, and had occasional spontaneous movements of the right arm and leg, with no movement at all of the left arm and leg. There were contusion and hematoma of the scalp in the right temporal region and some bleeding from the right ear. Her pupils were moderately dilated, equal and regular, with good reaction to light, and there was a tendency to left-sided deviation of the eyes associated with deviation of the head to the left. The other cranial-nerve functions were grossly normal. The reflexes were overactive on both sides, and there was a questionable Babinski response on the right. The pulse was rapid and of fair quality, and the systolic blood pressure was 130, with no readable diastolic pressure. Breathing was deep and labored and within a few minutes stopped altogether. Artificial respiration was started, and she was given oxygen. We believed that she had a probable compound basal fracture on the right, with some brain contusion, and extradural hemorrhage on the right side. The outlook regarding recovery seemed to be very poor. She was taken at once to the operating room, and a right subtemporal exploration was made without anesthesia. The usual incision emptied out a large scalp hematoma, and showed moderate contusion of the temporal muscle but no apparent fracture line. Removal of the bone showed no extradural bleeding or clot. The underlying dura mater was tense, and there was a slight, bluish discoloration. No free blood or clot was found when the dura was opened. The underlying brain was swollen and edematous, and there were no pulsations to be seen. The dura was opened widely, and the subdural space was explored carefully with a flat, narrow brain retractor so that an area about 10 cm in diameter was investigated, but no blood or clot was found, and there was no apparent

hygroma. After these procedures, the brain seemed to be much less swollen and edematous, and it resumed its normal pulsations. Soon after the dura was opened the child began to breathe of her own accord. The dura was left open, and the wound was closed in the usual way. Within a few hours the girl was fully conscious, oriented, co-operative and apparently well. The positive Babinski response persisted for about twenty-four hours, but after that time no neurologic abnormality could be made out. X-ray films of the skull showed a linear fracture of the frontal bone and the temporal defect left by the operation, no fracture was evident in the cervical spine. A lumbar puncture was done on the fourth day, with entirely normal findings. During her hospital stay the youngster had no remaining evidence of brain damage and was bright and happy. She was discharged on the eighteenth day and has stayed well since that time.

I cannot believe that an extradural clot not found at operation, and lying either well in front of or behind the area explored, as suggested by Gross and Ehrlich,⁹ could account for the focal signs shown by this patient, nor can I believe that, with complete recovery within a few hours, there was time for the removal of such a clot by the slow absorption described by them.

The following account, then, probably best explains the pathologic conditions present in this patient. The loss of consciousness coming on at the time of the injury was due to brain concussion, the exact nature of which has not, as yet, been satisfactorily determined. The child recovered from this and then developed signs of compression of the motor cortex characteristic of a rapidly expanding lesion. The three stages of physical compensation, venous congestion and capillary anemia, so well described by Trotter,¹⁰ came on in quick succession. The compression then spread more widely and involved the medullary centers. Swelling and edema of the brain, sufficient to account for capillary anemia, were actually seen in an area where lack of blood supply would cause the focal signs that had been noted. When the pressure was relieved, the vital centers regained their normal functions almost at once, the edema of the brain was seen to subside, and the signs of cortical ischemia were lost in a few hours. It is probable that a process such as this can only be shown in the operating room, even if there should be opportunity for post-mortem examination, it seems unlikely that the condition would last long enough to be evident to the pathologist. I believe that the findings in this last patient indicate the actual occurrence of acute focal edema of the brain.

SUMMARY

Observations made on a series of 7 children, having signs and symptoms strongly suggesting those caused by extradural hemorrhage, but with such rapid and complete recovery without operation as

to cast doubt on this diagnosis, are reported. With particular reference to the time elements present, consideration of various pathologic processes that might be expected to bring about such a clinical picture leads to the conclusion that acute cortical edema, with associated capillary anemia, best explains the condition. This view is supported by the reports and comments of other writers. The finding of visible edema in the region of the motor cortex at operation on an eighth child is reported, and it is believed that this confirms the explanation previously made. In my opinion, acute focal edema of the brain can occur in children with head injuries, and I regard it as a recognizable clinical entity.

EXTRARENAL AZOTEMIA

Report of a Severe Case with Recovery

CHARLES F APPEL, M D,* AND JAMES H TOWNSEND, M D†

CAMBRIDGE, MASSACHUSETTS

AS FAR back as 1912 From and Marie¹ reported the occurrence of prerenal azotemia in cholera-form enteritis. Similar observations of prerenal azotemia were made by Nobécourt, Bidot and Maillet² in gastrointestinal disturbances in infancy in 1912 and by Tileston and Comfort³ in intestinal obstruction with vomiting in 1914. Only in recent years, however, has this condition been more completely understood.

The characteristic picture of extrarenal azotemia is that of renal failure without actual renal disease or of renal disease not sufficient to explain the signs of renal failure present. The more important signs of extrarenal azotemia include an elevation of the nonprotein nitrogen of the blood, uremic odor of the breath, dehydration, loss of electrolyte (particularly the chloride ion), and oliguria or anuria. The eye-grounds, on the other hand, appear normal, the blood pressure is not elevated, and the specific gravity of the urine is not markedly diminished, if at all lowered. Casts, red cells and white cells may be present in the urine, but these characteristically disappear.

The conditions in which extrarenal azotemia may occur are numerous, the following being mentioned by Jeghers and Bakst⁴: coronary thrombosis, alkalosis, pyloric obstruction, peritonitis, liver-kidney syndrome, yellow fever, gastrointestinal hemorrhage, postoperative complications, congestive heart failure, reaction to transfusion and intravenous therapy, Weil's disease, Addison's disease, pneumonia, allergy, diabetes mellitus, shock, acute

pancreatitis, diarrheal disease, heat cramps, drug intoxication, and burns.

In 1941 Garis⁵ reported a case of prerenal uremia due to papilloma of the rectum. In the same year Layne and Moir⁶ reported several cases of extrarenal uremia, an unusual one being a case of tabetic crisis with persistent vomiting. O'Donovan,⁷ in 1944, described 2 cases of extrarenal azotemia resulting from pyloric obstruction.

It is believed that the elevation of the nonprotein nitrogen of the blood in prerenal azotemia originates from one or both of two sources: an impaired elimination of the nonprotein nitrogenous products of the blood, or an increased production of these products. Jeghers and Bakst⁴ described the following basic causes of extrarenal azotemia: a drop in blood pressure, hypochloremia and hyponatremia, dehydration, liver damage, and protein catabolism. All factors need not be present in the same patient, but sometimes a combination of conditions or even a single one is sufficient to produce prerenal azotemia.

Fishberg⁸ considers a similar group of factors: hypochloremia, low arterial pressure, toxic nephritis, and alkalosis. Furthermore, Fishberg believes that the primary pathogenic factor in most — if not all — cases of prerenal azotemia with impaired renal function is a diminution of blood flow through the kidneys. This appears to be true of the causes enumerated by Jeghers and Bakst.⁴

A drop in systemic blood pressure reduces the blood flow through the glomeruli, diminishes the urine volume and, if of sufficient magnitude, results in azotemia. Hypochloremia and hyponatremia

*Resident in medicine Mt. Auburn Hospital.

†Chief Medical Services Mt. Auburn Hospital.

are generally related to excessive loss of fluid (as in persistent vomiting, diarrhea or perspiration). With the resultant dehydration, there is a diminished blood volume, hemoconcentration, reduced blood flow through the glomeruli, and impaired glomerular filtration.

According to Jeghers and Bakst,⁴ patients with azotemia and liver damage have had inadequate study for hypochloremia, hyponatremia and low blood pressure to determine whether liver damage per se produces azotemia.

Fishberg⁹ believes that protein catabolism increasing the blood nonprotein nitrogen occurs

lytic therapy is difficult to explain on this basis. Alkalosis is frequently associated with vomiting, and in those cases the mechanism could be explained by dehydration.

The common denominator, then, in the pathogenesis of prerenal azotemia appears to be diminished blood flow through the kidneys, which fortunately is reversible in many cases, provided treatment is started early. On the other hand, if treatment is instituted too late or is inadequate, irreversible renal damage may occur.

In the following case the signs of severe renal failure were caused by the mechanism described

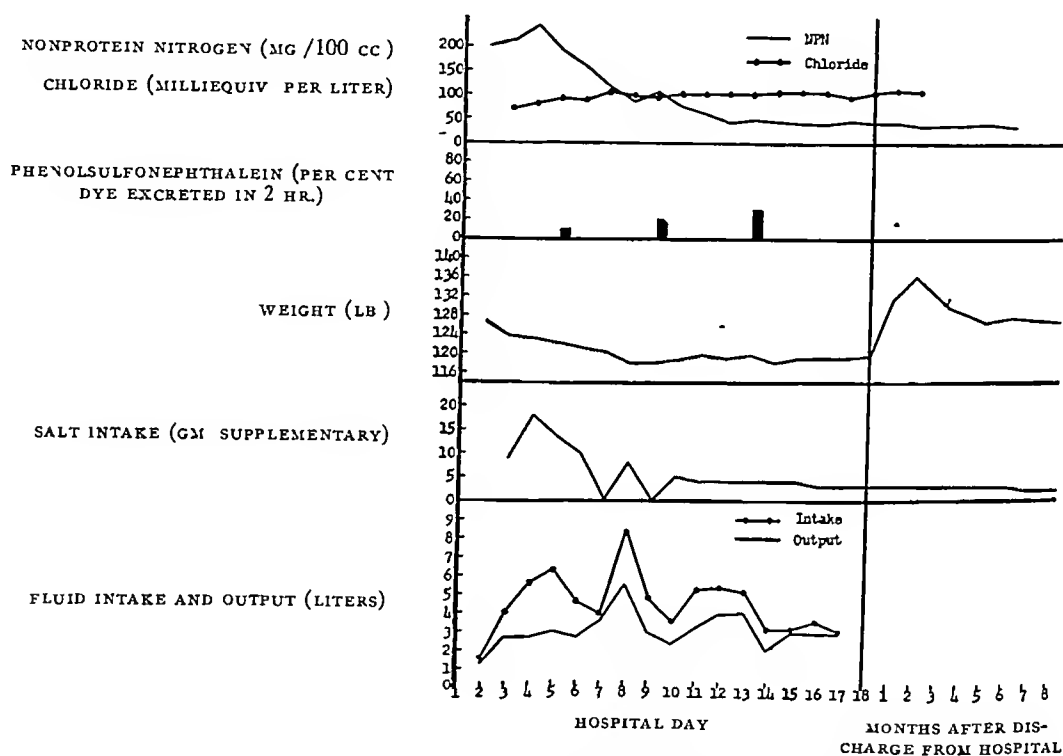

FIGURE 1 Course of the Blood Nonprotein Nitrogen and Chloride, Phenolsulfonephthalein Excretion Test, Body Weight, Supplementary Salt Intake and Fluid Intake and Output in the Hospital and during the Eight Months' Follow-up Period

if there is associated impaired function. He cites the example of urea given to a patient with normal kidneys in amounts exceeding that of accelerated protein catabolism without producing an increase in urea of the blood. His final conclusion is that "when considerable azotemia is present renal excretion is subnormal."

In the review of the factors enumerated by Fishberg⁸ presented above, hypochloremia and low arterial pressure were discussed. The conception of toxic nephritis is a hypothetical one. Damage to the kidneys, as through acute infections, is supposed to occur by circulating toxins in the blood. These have not been demonstrated, and, furthermore, the response to hydrotherapy and electro-

above. After intensive therapy the renal function returned to normal.

CASE REPORT

J. D., a 37-year-old rubber-factory worker, was admitted to the hospital on January 26, 1947, with the chief complaint of abdominal pain of 15 days' duration. While he was at work on the night shift in the hot and moist environment of a rubber factory, severe frontal headaches followed by a chilliness and continuous anorexia, and nausea without the following morning he vomited material that was not grossly bloody. Shortly afterward a sharp pain appeared in the lower abdomen near the midline, shifting at times to the epigastrium but with no relation to meals. There was also inconstant and transient pain in the lumbar region, radiating anteriorly to the lower abdomen. The patient remained in bed at home, but his condition became worse. The abdominal pain became more severe, and the nausea, vomiting and headache persisted unabatingly. Eight days before admission the patient summoned his family physician,

who believed he had a peptic ulcer and prescribed a regime of milk, cream and "amphojel." Nevertheless, the symptoms continued, so that hospitalization was finally recommended. There was no history of hematemesis, jaundice, melena, clay-colored stools, constipation or diarrhea.

The patient had noted bleeding from the gums for the past week, and on the day of admission, he had an episode of epistaxis, which stopped spontaneously. Although there was no history of dysuria or hematuria, he had usually drunk about 3 quarts of water while at work for the past 1½ years. However, his fluid intake was markedly reduced after the onset of the vomiting. Furthermore, according to the patient's wife, severe oliguria had begun 10 days before admission, but the exact degree of the oliguria could not be ascertained.

The past history gave no evidence of cardiac or renal disease, scarlet fever or frequent sore throats.

Physical examination revealed a fairly well nourished and well developed man, moderately dehydrated and drowsy, lying flat in bed without dyspnea or cyanosis and not answering questions readily. There was a pterygium of the left eye and a subconjunctival hemorrhage below the right iris. Fundoscopic examination disclosed no choking of the disks and no hemorrhage, exudate or spasm of the arteries. There were dried blood clots in the right naris, and generalized gingival bleeding, with reddish discoloration of the tongue. No abnormal findings were present in the chest. The blood pressure was 144/90. On deep palpation there was slight tenderness in the epigastrium and moderate tenderness at both costovertebral-angle areas. Rectal examination revealed no abnormal masses. Although the gloved finger showed no evidence of gross blood, the specimen yielded a ++ guaiac test for occult blood.

The initial impression was that the patient had a bleeding peptic ulcer and possibly a vitamin C deficiency, or some form of blood dyscrasia. Therefore, he was placed on a regimen of Meulengracht diet, "gelusil," tincture of belladonna and large doses of vitamins.

On the 2nd hospital day the patient continued to be drowsy and to complain of pain in the lumbar region, radiating to the lower abdomen. The prothrombin time was 16 seconds (normal, 17 to 22 seconds), the bleeding time was 2 minutes and 7 seconds, and the clotting time, 4 minutes and 1 second. The red-cell count was 5,050,000, with a hemoglobin of 15 gm, and the white-cell count 11,300, with a normal differential count. The blood nonprotein nitrogen was 200 mg per 100 cc. Urinalysis showed a trace of albumin with 8 to 10 white cells and 30 to 40 red cells per high-power field in the sediment. In view of the clinical picture and laboratory findings, the plan of treatment was changed to increase substantially the daily fluid and electrolyte intake.

Figure 1 demonstrates the hospital course, showing how the blood nonprotein nitrogen rose to 245 mg per 100 cc and then fell gradually to normal, remaining so. The fluid intake was entirely by mouth except on the 3rd hospital day, when 1000 cc of 5 per cent glucose in physiologic saline solution and 1500 cc of 5 per cent glucose in distilled water was given intravenously. The carbon dioxide combining power fell from 32.6 milliequiv on the 3rd hospital day to 23.0 milliequiv per liter (normal, 23 to 30 milliequiv) on the 8th hospital day. Subsequent urinalyses showed specific gravities in the realm of 1.010 with traces of albumin, a few white and red cells and occasional granular casts. The blood pressure remained constant at about 134/84 throughout the hospital course.

An electrocardiogram on the 4th hospital day showed a sinus bradycardia at a rate of 50 per minute, with left-axis deviation, but a second tracing 13 days later was entirely normal. On the 5th hospital day the serum protein was reported as 7.2 gm, the albumin as 4.6 gm, and the globulin as 2.7 gm per 100 cc, with an albumin-globulin ratio of 1.8. A barium enema on the 7th hospital day showed the barium to pass freely to the cecum. There was no evidence of carcinoma or diverticulitis. A chest x-ray film disclosed no abnormalities of the heart or lungs. On the same day a stool examination demonstrated no ova, parasites or blood. By the 9th hospital day the patient had become stronger, with improved appetite, so that he was allowed to be ambulatory. An intravenous pyelogram on the 12th hospital day showed normal-appearing calyces, pelves and ureters and normal excretory function. The blood phosphorus was reported as 4.1 mg per 100 cc on the 16th hospital day, and an upper gastrointestinal series was entirely normal.

The patient was discharged on the 18th hospital day on a regime of supplementary salt of 4 gm and 10 glasses of water a day. His follow-up course in the outpatient department was uneventful (Fig 1). Urinalyses done 2, 4 and 6 months after discharge revealed clear urine with specific gravities of 1.025, 1.020 and 1.018 respectively.

DISCUSSION

The unusual feature of this case was the extremely high nonprotein nitrogen that fell from 200 to 42.5 mg per 100 cc after ten days of intensive electrolytic therapy and hydrotherapy. At no time during this treatment could the output be considered low. The significance of alkalosis could not be ascertained altogether. While the patient was in the hospital, alkalosis was never more than slight. Its magnitude before admission, on the other hand, might have been more marked, but unfortunately was not known. The blood pressure remained constant around 134 systolic, 84 diastolic. It never reached the low levels of traumatic shock or severe transfusion reaction.¹⁰ The return of renal function to normal was shown by an excretion of 60 per cent of phenolsulfonephthalein in two hours (compared with 20 per cent excretion of the dye eight days previously) and by the normal excretion of dye in the intravenous pyelogram four weeks after the onset of the illness. Furthermore, the sustained normal nonprotein nitrogen and the specific gravity of 1.025 and 1.020 two and four months after the onset of illness helped to substantiate the return of renal function to normal.

The rationale in therapy was to restore the continued loss of fluids and electrolytes as soon as possible by the increased fluid and sodium chloride intake by mouth and by infusions of glucose and physiologic saline solution intravenously. In this way hemoconcentration and dehydration were reduced, blood flow through the glomeruli increased and normal renal excretion restored.

SUMMARY

The occurrence and pathogenesis of extrarenal azotemia are discussed.

A case of severe prerenal azotemia preceded by dehydration and moderate intake of alkalis, and followed by return of renal function to normal after intensive electrolytic treatment and hydrotherapy, is presented.

are generally related to excessive loss of fluid (as in persistent vomiting, diarrhea or perspiration). With the resultant dehydration, there is a diminished blood volume, hemoconcentration, reduced blood flow through the glomeruli, and impaired glomerular filtration.

According to Jeghers and Bakst,⁴ patients with azotemia and liver damage have had inadequate study for hypochloremia, hyponatremia and low blood pressure to determine whether liver damage per se produces azotemia.

Fishberg⁹ believes that protein catabolism increasing the blood nonprotein nitrogen occurs

lytic therapy is difficult to explain on this basis. Alkalosis is frequently associated with vomiting, and in those cases the mechanism could be explained by dehydration.

The common denominator, then, in the pathogenesis of prerenal azotemia appears to be diminished blood flow through the kidneys, which fortunately is reversible in many cases, provided treatment is started early. On the other hand, if treatment is instituted too late or is inadequate, irreversible renal damage may occur.

In the following case the signs of severe renal failure were caused by the mechanism described

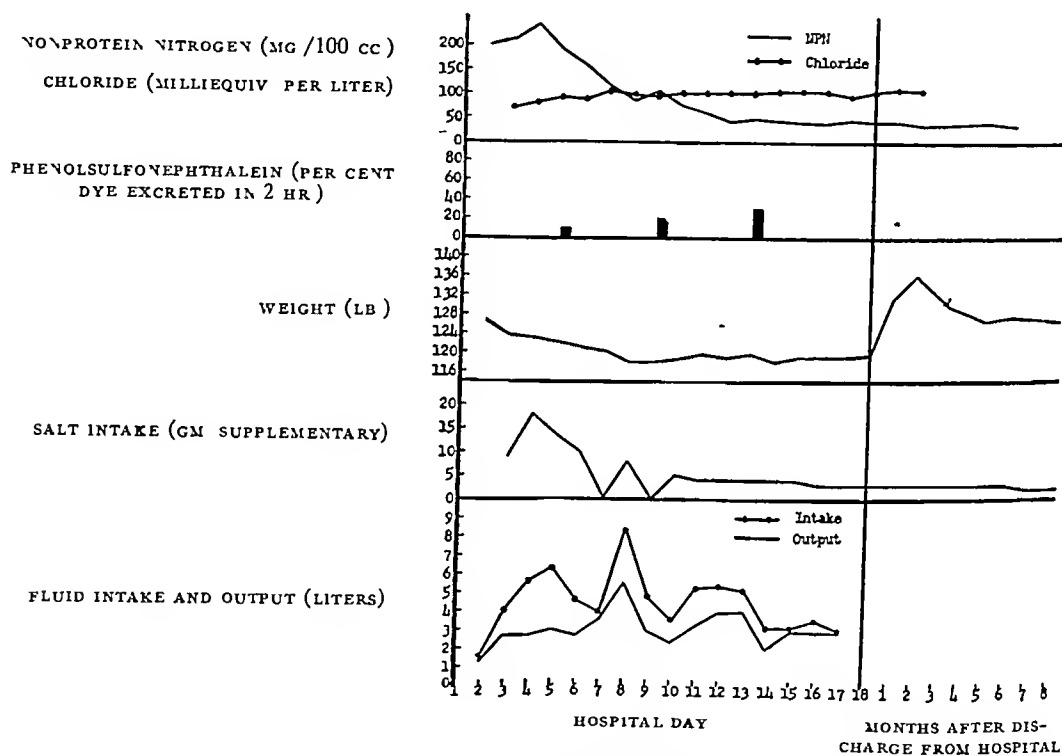

FIGURE 1 Course of the Blood Nonprotein Nitrogen and Chloride, Phenolsulfonephthalein Excretion Test, Body Weight, Supplementary Salt Intake and Fluid Intake and Output in the Hospital and during the Eight Months' Follow-up Period

if there is associated impaired function. He cites the example of urea given to a patient with normal kidneys in amounts exceeding that of accelerated protein catabolism without producing an increase in urea of the blood. His final conclusion is that "when considerable azotemia is present renal excretion is subnormal."

In the review of the factors enumerated by Fishberg⁸ presented above, hypochloremia and low arterial pressure were discussed. The conception of toxic nephritis is a hypothetical one. Damage to the kidneys, as through acute infections, is supposed to occur by circulating toxins in the blood. These have not been demonstrated, and, furthermore, the response to hydrotherapy and electro-

above. After intensive therapy the renal function returned to normal.

CASE REPORT

J. D., a 37-year-old rubber-factory worker, was admitted to the hospital on January 26, 1947, with the chief complaint of abdominal pain of 15 days' duration. While he was at work on the night shift in the hot and moist environment of a rubber factory, severe frontal headaches followed by a chilliness and continuous anorexia, and nausea without abdominal pain developed. He continued to work, but on the following morning he vomited material that was not grossly bloody. Shortly afterward a sharp pain appeared in the lower abdomen near the midline, shifting at times to the epigastrium but with no relation to meals. There was also inconstant and transient pain in the lumbar region, radiating anteriorly to the lower abdomen. The patient remained in bed at home, but his condition became worse. The abdominal pain became more severe, and the nausea, vomiting and headache persisted unabatingly. Eight days before admission the patient summoned his family physician,

in whatever tissues it might be found. The fourth was to apply the agent in controlled clinical studies and to evaluate by sound statistical methods the results of therapy.

What has thus far been said applies to all chemotherapy. The following sections review recent advances in understanding and employment of chemotherapy directed in particular against bacterial infections. The four steps outlined above serve as framework for the discussion of chemotherapeutics in general use, after which some that are presently in the developmental stage are briefly reviewed.

IN VITRO STUDIES AND MECHANISM OF ACTION

Prior to 1935 a great number of inorganic and organic substances were known to inhibit the growth of micro-organisms or to kill them. Metallic ions, phenols, aliphatic alcohols, organic acids, dyes, oxidizing agents, soaps and detergents are classes of compounds displaying an antiseptic or, at higher concentrations, a disinfectant action. These agents vary considerably in specificity for different organisms, the gram-positive group being, in general, most readily attacked. Logarithmic killing curves are obtained with adequate concentrations, and the death rate is critically related to concentration. The deficiency of all these substances lies in their indiscriminate affinity for a multitude of host proteins along with those of pathogenic organisms, a circumstance that led to the vague and inexact descriptive term "general protoplasmic poisons." Their unfavorable chemotherapeutic ratio restricts their use (with the exception of a few dyes and organic acids) to topical applications and sterilization of inanimate objects.

Sulfonamides

Domagk's introduction of prontosil¹³ and the subsequent use of the sulfonamides (Fig. 1) was remarkable not because this class of compound was more potent than the antiseptics in inhibiting bacterial growth. On the contrary, comparable concentrations of phenolic compounds and mercuric chloride accomplish the same end-result, whereas the newer cationic detergents are effective at less than 0.5 mg per 100 cc.⁹⁻¹² The remarkable fact was that the effective sulfonamide concentrations should be tolerated, in body fluids without prohibitive toxicity. Thus was the era of systemic antibacterial chemotherapy inaugurated.

The sulfonamides are often stated to be purely bacteriostatic. There is clear evidence, however, that although low concentrations inhibit growth, higher concentrations cause a progressive reduction in the viable count.¹⁴ The bacteriostatic effect is not immediate in onset but occurs only after several cell divisions in the presence of the drug. If nongrowing organisms are suspended in a sulfonamide solution and then removed and placed in a normal growth medium the drug is without effect.¹⁵

The bactericidal action likewise appears only in a medium favoring growth. The respiration of nongrowing cells is not affected,^{16, 17} but the additional respiration entailed in growth is inhibited.^{16, 18} The suggestion that bacteriostasis is secondary to this inhibition of respiration is neither more nor less valid than the view that the latter is the result of the former.

The inactivity of the sulfonamides in the presence of pus and tissue extracts soon led to the isolation of para-amino-benzoic acid (PABA), which competitively antagonizes sulfonamide action.^{19, 20} The idea that these drugs blocked the normal bacterial

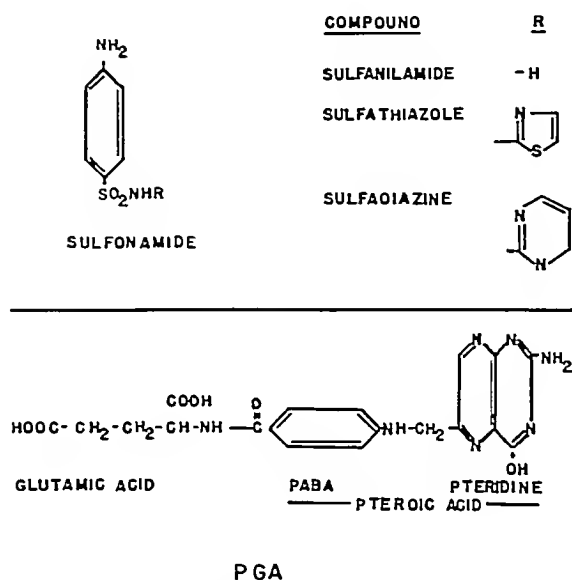

FIGURE 1 Structural Formulas of Some Sulfonamides and Pteroylglutamic Acid (Folic Acid)

utilization of PABA¹⁵ gave impetus, through the Woods-Fildes theory^{19, 21, 22} to the whole fruitful study of biologic antagonisms.^{23, 24} It was finally confirmed by the discovery of folic acid²⁵ (pteroylglutamic acid, PGA) as an essential substrate in the growth of many bacteria. This compound (Fig. 1) is a conjugated molecule containing one residue each of glutamic acid, PABA and a base (pteridine). That sulfonamides prevent the incorporation of PABA into the PGA molecule now seems established beyond reasonable doubt. Organisms that are entirely independent of the need for PGA are not sensitive to sulfonamides. Organisms that require *ready-made* PGA as a "growth factor" are also insensitive to sulfonamides, since they lack the metabolic step upon which the drug acts²⁶, PGA analogues, however, inhibit their growth.^{27, 28} Sulfonamide-sensitive organisms are evidently those that must form their own PGA from PABA. Sulfonamide growth inhibition in such organisms is relieved *either* by PABA *or* by PGA.

MEDICAL PROGRESS

ANTIBACTERIAL CHEMOTHERAPY*

AVRAM GOLDSTEIN, M D †

BOSTON

IT IS an interesting commentary on one man's impact upon the growth of scientific medicine that a review of a rapidly expanding field, written thirty-five years after his death, should comprise a mere addition of details to the broad guiding principles he established. In this thirteenth year of the clinical use of sulfonamides, the seventh of penicillin and the fourth of streptomycin, it seems entirely appropriate to introduce the discussion by a restatement of the fundamentals upon which Ehrlich¹⁻³ founded the science of chemotherapy.

As intended by its author, the word "chemotherapy" means the treatment of parasitic disease by direct chemical attack upon invading organisms—viruses, fungi, bacteria, spirochetes, protozoa or helminths. In my opinion extending this meaning to include the treatment of a variety of pathologic states (for example, "chemotherapy of heart disease") blurs a distinction that is as fundamental today as when it was first introduced by Ehrlich. It is precisely the killing of pathogenic forms of life with a *minimum* of effect upon the tissues and physiologic processes of the host that is the unique goal of chemotherapy. All drugs that may be employed to this end are referred to below as "chemotherapeutics,"† arbitrary distinctions between molecules produced in the laboratory and those (the so-called antibiotics⁶) whose synthesis the organic chemist has not yet achieved being avoided.

Chemotherapeutics do not act primarily upon the host but rather combine chemically with certain systems of parasitic organisms. Ehrlich showed that affinity for a parasite often requires a very exact structure in a drug, whose entire potency may hang upon addition or removal of a single atom. He summarized the high degree of specificity of this combination in his well known "receptor" or "side-chain" hypothesis.⁷ From the concept that chemotherapeutic action is fundamentally a chemical combination came two important corollaries: that the basic phenomena should be amenable to study in the isolated parasite, in vitro, wherever the organism could be grown, and that stoichiometry or mass law relations, or both, must apply as in

any chemical reaction—that is, for a given system a definite total dosage or concentration, or both, will be required for complete combination with the organisms.

Ehrlich early realized that although a great many drugs were effective at some concentration in vitro, toxicity for the host might prevent their systemic utilization. When he had shown, however, that affinity for parasite (parasitotropism) and for host tissues (organotropism) by no means went hand in hand, the way was opened for molecular modifications that would increase the former or decrease the latter affinity. Ehrlich's view that drugs also combined with tissue cells through receptor side chains was an adequate expression of the facts at a time when the specificity of protein interactions was still dimly understood. Today the same views could be reformulated in terms of enzyme-mediated steps in metabolic processes—some playing a role in both parasite and host, and others being unique to each organism or host tissue.

The practical implications of specific and differential toxicity to parasite and host were summarized in Ehrlich's *chemotherapeutic ratio*.¹ The criterion of usefulness of a chemotherapeutic is not in its absolute molar potency against the parasite but only in the *ratio* of dose first producing toxic effects in the host to that required to kill the parasite. *Comparisons between chemotherapeutics on a gravimetric basis are without significance in foretelling their possible clinical value.*

Thus, Ehrlich's work led to a clearly formulated approach to the development of agents useful in clinical chemotherapy. The first main step was to discover by isolation or synthesis compounds that would effectively kill the parasite at some reasonable concentration in vitro, and to study the mechanism of interference by such agents with the metabolic pathways. The second was to select drugs that would yield a satisfactory chemotherapeutic ratio—that is, agents sufficiently nontoxic to be of clinical promise—and to investigate the means of reducing toxicity, by modification of structure or otherwise. The third was to work out the practical pharmacodynamics—that is, the fate of the drug in the body—to determine the optimal dose, route and frequency of administration, and other special methods for bringing the drug into full chemical combination with the parasite,

‡The word appears in the designation of a Committee of the National Research Council⁴ during the war years and has been advocated more recently by Dr. B. D. Davis.⁵

at this task. The various penicillins* were shown to differ in the substituent acid coupled to the alanine amino-group.⁵¹⁻⁵² It was demonstrated that the type of penicillin produced varied with the substrate supplied — phenylacetic acid, for example, being coupled to yield benzyl penicillin. When isotopically labeled phenylacetylvaline was supplied, only the phenylacetyl portion was incorporated, demonstrating that the unique portion of the penicillin molecule is synthesized separately and coupled as a unit to any one of a number of organic acids.⁵³ The ring-condensed amino-acid portion can be synthesized, at least in part, from simple materials since labeled sulfur, supplied as sulfate, is recovered quantitatively in the penicillin molecule.⁵⁴

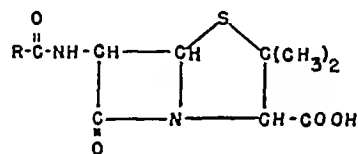

The penicillins are moderately strong acids whose sodium, potassium, calcium or other salts may be used therapeutically. The carboxyl group must be free and ionized, esterification destroying the entire activity of the molecule.⁵⁵ Two comprehensive reviews of penicillin chemistry have recently appeared.⁵⁶⁻⁵⁷

A remarkable preferential affinity for gram-positive organisms and spirochetes is shared by all the penicillins. That there are quantitative differences is established, p-hydroxybenzyl penicillin (X), for example, is more potent than benzyl penicillin (G) against most organisms.⁵⁸⁻⁶¹ But the general pattern of affinities is the same, and the differences have not appeared substantial enough to warrant large-scale commercial production of other types than penicillin G, which is now available in pure crystalline form, requires no refrigeration and is of standard potency.⁶² In accordance with established procedure the unit should long since have been dropped.

An interesting sidelight on the purification of penicillin is the finding by Hobby and her collaborators⁶³ that in some respects the protective action of crystalline benzyl penicillin is inferior to that of the cruder material in experimental animal infections. It has been suggested that the original mixture contained impurities of an antitoxic nature,⁶²⁻⁶⁴ that phenylacetic acid, which is known to potentiate penicillin action, was the responsible agent,⁶⁵ or that specific metabolic inhibitors were present.⁶⁶

Penicillin is bacteriostatic in threshold concentration and bactericidal in higher concentration.⁶⁷⁻⁶⁹ Neither effect is observed unless cells are growing,¹⁴⁻⁶⁷ and the killing action is most pronounced against young, rapidly growing organisms.¹⁴⁻⁷⁰ It is enhanced by substances and conditions that promote growth.⁷⁰ Cells exposed to penicillin show characteristic morphologic abnormalities, notably giant forms that fail to divide.¹⁴⁻⁷¹ It had been thought that the bactericidal effects of the drug resembled those of some of the common disinfectants.

But Eagle⁷²⁻⁷³ has recently shown, confirming earlier work by Hobby,⁶⁷ that the rate of killing does not follow increasing concentration beyond a certain point. Unlike disinfection, therefore, the bactericidal effect seems to depend upon the degree of blocking of a vital system whose complete saturation results in a constant maximal death rate. The onset of bacteriostasis is preceded by a short

lag period,¹⁴ and a prolonged lag is observed before growth resumes when organisms are transferred to fresh medium after brief exposure to the drug.⁷⁴⁻⁷⁶ Respiration is not inhibited except under conditions favorable to growth.⁷⁷⁻⁷⁸ These findings are all so similar to those obtained with the sulfonamides that it is difficult to substantiate the earlier consensus that the action mechanisms of penicillin and the sulfonamides differed fundamentally from one another.

The ingenious studies of Pratt and DuRenoy,⁶⁵⁻⁷⁹⁻⁸¹ who investigated the chemical reactivities of various portions of typical penicillin agar assay plates, showed that the drug promotes a shift of -SH to S-S and of aldehyde or enol to ketone, suggesting a primary interference with oxidation-reduction systems. These workers demonstrated that the zone of increased growth at the margin of an inhibition zone, corresponding to just subthreshold penicillin concentration, was the area in which the biochemical shifts described were most active. It is significant that by their methods the authors were unable to show any qualitative differences in the action of "sensitive," gram-positive and "insensitive," gram-negative organisms, provided only

*As is customary the word penicillin unless qualified is used here to denote penicillin G — benzyl penicillin.

Dr. Robert H. Allen
M. D. A. Medical College

itself. As one might expect, the antagonism produced by the former is competitive, growth inhibition depending upon the ratio of PABA to sulfonamide. On the contrary, in the presence of PGA, sulfonamide is without effect, regardless of concentration, within limits. The antagonisms cited here have been demonstrated not only for bacteria but also for psittacosis virus, whose growth on embryonated eggs is inhibited by sulfonamides and restored by PABA or PGA.²⁹

This scheme explains the characteristic lag of several cell divisions before growth inhibition by sulfonamides occurs; it is assumed that PGA stores are being exhausted during this period, the synthesis of new PGA being blocked at once.²² The role of PGA in growth and metabolism, however, and in particular its curious connection with human erythropoiesis^{30, 31} are not understood. Furthermore, the relations may not be as simple as these generalizations indicate, since exceptions to the rules have been observed in certain organisms. It is also demonstrated that a number of compounds unrelated to PGA (methionine, xanthine and serine) are capable of antagonizing sulfonamide action noncompetitively, indicating that several enzymatically controlled steps may be successively inhibited by the drug.³²⁻³⁶ Moreover certain important respiratory enzymes are inhibited at reasonable sulfonamide concentrations.³⁷ The best summary of the evidence implicating systems other than the PABA → PGA reaction can be found in Henry's³⁸ review of five years ago.

Kumler and Daniels³⁹ attempted to explain the varying potencies of the different sulfonamides on the basis of resonance effects. Bell and Roblin⁴⁰ made a similar correlation between pK and potency, and made the interesting prediction that sulfadiazine (Fig 1) already possessed optimal antibacterial activity and could only be improved upon with respect to other pharmacologic properties (such as toxicity). This prediction was apparently correct. Of the newer systemic sulfonamides only sulfamerazine (monomethyl sulfadiazine) and sulfamethazine (dimethyl sulfadiazine) have merited widespread clinical trial, and neither is intrinsically more potent than sulfadiazine. Nor, in general, have various sulfonamides displayed appreciable differences in bacterial affinities (provided only that the para-amino group remain free), molecular changes in the N₁ substituent serving to modify quantitative rather than qualitative antibacterial properties.

Gramicidin, Tyrocidine and Tyrothricin

From a chronologic point of view the next potential chemotherapeutics to appear were tyrocidine and gramicidin, which Dubos⁴¹ obtained from *Bacillus brevis* by isolation from the crude mixture, tyrothricin. These compounds were shown to be bactericidal, preferentially against gram-positive

forms, and also to display a hemolytic action that, among other toxic features, prevented their systemic use.⁴² Gramicidin (or tyrothricin) is still employed to some extent in the treatment of surface infections caused by gram-positive cocci. Tyrocidine acts, in every respect, like a disinfectant, it markedly inhibits cell respiration and disrupts the bacterial cell wall. Gramicidin, on the other hand, inhibits growth, does not lyse bacteria and stimulates the oxygen uptake of nongrowing cells.⁴³ In view of these differences it is interesting that they should have become prototypes of the large group of substances now classed as "antibiotics"—a fine illustration of the fact that biologically produced antibacterials as a group have no unique mechanism of action.

Gramicidin and tyrocidine have proved unusually interesting from the structural standpoint. They are cyclic peptides containing a number of residues of various amino-acids, some being of the unusual d-configuration.⁴² Investigation by the newer techniques of counter-current distribution and paper chromatography has revealed at least four different gramicidins.⁴⁴ The major component contains l-tryptophane, d-leucine, d,l-valine, l-alanine, l-glycine and ethanolamine. The others differ in respect of one or more amino-acids. The minimal molecular weight appears to be approximately 8700, representing about 70 residues. Tyrocidine yields, on hydrolysis, ornithine, proline, valine, leucine, tryptophane, tyrosine, aspartic acid and glutamic acid of the usual configurations, and d-phenylalanine. Gramicidin-S consists of but five amino-acids, l-ornithine, proline, valine, leucine and d-phenylalanine.⁴⁵ As pointed out below, these unusual polypeptide arrangements prove to be typical of a number of naturally occurring antibacterial substances. The mechanisms whereby compounds of this type produce growth inhibition in one case and lyse a cell wall in another and the significance of the ever-present d-amino-acid, remain equally obscure.

Penicillins

The advent of penicillin^{46, 47} provided a clinical weapon of unsurpassed excellence not, again, because of its higher molar potency, but because its toxicity is negligible even at doses fantastically higher than those required for minimal antibacterial effect. The need to produce the drug biologically and in vast quantities to meet war requirements stimulated considerable research into its structure and the optimal conditions for its synthesis by the mold.⁴⁸ The first line of endeavor led to the surprising result⁴⁹ that the drug is (or appears to be) a curious ring condensation of two amino-acids—alanine and beta-dimethyl-cysteine (Fig 2). The structure was later confirmed by a token synthesis,⁵⁰ but the mold is still more efficient than the chemist

drugs of this class the hydrolyzed residues display little if any of the original activity. The significance of the hexose and glucosamine components¹¹⁴ is not clear, nor the meaning of the similarity of the streptidine portion¹¹⁵ to the B vitamin inositol. From the observed increase in potency with pH it is inferred that the basic guanido groups of streptidine confer optimal properties in their uncharged state.

It has been observed¹¹⁶ that streptomycin can precipitate as a complex with deoxyribosenucleic acid (DNA), a fact that raised interesting possibilities in view of the intimate connection of the latter compound with protein-synthetic processes. Other investigators,¹¹⁷ however, showed that the complex actually dissociated at physiologic saline concentrations, that phosphate had opposite actions on the DNA-streptomycin complex and the antibacterial affinity of the drug, and that the enzyme deoxyribonuclease, which depolymerizes the complex, has no effect upon streptomycin potency. These facts call the significance of the action of the drug upon DNA into considerable question, the investigators also pointing out that viruses of the psittacosis-lymphogranuloma group, which are rich in DNA, are also relatively insensitive to streptomycin. Complex formation with ribonucleate has also been reported,¹¹⁸ and is discussed below.

Like penicillin, streptomycin is antagonized by a number of compounds. Anaerobic conditions or the presence of glucose reduces its potency but this is primarily the result of increased acidity.¹¹⁹⁻¹²⁰ Bivalent cations (magnesium, calcium and barium) and certain anions (phosphate, sulfate, citrate and tartrate) are competitive antagonists.¹¹⁷ Ascorbic acid and sulfhydryl compounds like cysteine and thioglycollate are also antagonists,¹²⁰⁻¹²³ whether they act by lowering the redox potential of the medium is not clear, but such an interpretation would be consistent with the greater sensitivity of aerobic than anaerobic bacteria.¹²⁴⁻¹²⁵

Along these lines, Cavallito and his co-workers¹²⁶⁻¹²⁷ have shown that penicillin, streptomycin and other complex antibacterial agents are capable of combining with certain thiols in isolated chemical systems. Whereas mercuric ion combines rather indiscriminately, penicillin and streptomycin are highly selective for -SH groups surrounded by proper reactive neighboring groups (for example, an amino-group separated from -SH by an exact number of carbon atoms). Once formed, the mercury complexes are readily reversed by other reactive thiols, but the penicillin and streptomycin complexes are not. The data are advanced in support of the view that combination with thiol groups mediates the antibacterial action of these drugs,¹²⁵⁻¹²⁹ a suggestion that is consistent with the findings of Pratt and Dufrenoy. The interesting observation has been made¹³⁰ that penicillin can be considered a structural analogue of glutathione, whose function

is thought to involve maintenance of reduced sulfhydryl groups.

Fitzgerald and Bernheim¹³¹⁻¹³² reported that the oxidation of benzoic acid by the tubercle bacillus is selectively inhibited by bacteriostatic concentrations of streptomycin and that this does not occur in resistant strains. Green, Iverson and Waksman¹³³ demonstrated interference by pyruvate or fumarate with streptomycin activity, an antagonism that is not shared by a number of other organic compounds. Rhymer et al.¹³⁴ showed that the structural analogue, lipositol, is a streptomycin antagonist. But none of these phenomena were shown to be related in a definite way to the action mechanism of the drug.

As Gaddum¹³⁵ has pointed out, there are two sharply defined categories of drug antagonism — one drug may compete with another for a receptor site, or one drug may form a chemical complex with another and thus prevent its combination (or if the affinity is great, remove it from combination). The PABA-sulfonamide antagonism is obviously of the first type and is thereby directly concerned with the drug's mechanism of action. A simple example of the second type is the neutralization of cationic by anionic detergents.¹³⁶ Antagonisms of this kind can give insight into the intimate manner of combination with cell receptors only by inference and deduction. Thus the demonstration that a sulfhydryl compound combines with a chemotherapeutic, or even reverses its action on the bacterial cell, suggests, *but does not prove*, that the drug acts by combining with bacterial -SH groups.¹³⁷ It must be concluded that, with the possible exception of the benzoic acid results, the work cited has yielded no proved antagonists of the first type. Consequently experiments with antagonists have as yet contributed little definitive information to knowledge of the sites and mechanisms of combination of penicillin and streptomycin with bacterial cells.

Mechanisms of Antibacterial Action

Broadly speaking, bacterial growth can be interrupted by interference with two main pathways: catabolic reactions yielding the energy required for protein synthesis, and the anabolic, synthetic processes themselves. To these should be added the special mechanisms that control cell fission and the reduplication of genetically functioning nucleoprotein.

The bacteriologic criterion of death is an irreversible inability to reproduce when the cell is introduced into fresh medium suitable for growth. It has proved difficult to make a sharp distinction between bacteriostatic and bactericidal action. If growth inhibition is prolonged, a logarithmic death phase sets in, indeed, a progressive loss of viability is observed even in a normal culture in the stationary phase, when growth has ceased.¹³⁸ The reproductive mechanism in bacteria appears

that a high enough penicillin concentration were used to inhibit growth of the latter. This points up the fact that sensitivity to most chemotherapeutics is relative, expressed in terms of a threshold concentration for growth inhibition.

One of the incidental findings in these experiments was the specific action of cobalt in enhancing penicillin activity *in vitro*⁸¹ and in experimental pneumococcal infection in mice.⁸² This may be another example of the penicillin-enhancing properties of substances that promote growth, in view of the recent report that vitamin B₁₂ is a cobalt complex.⁸³ Whether the curious phenomenon will prove clinically useful remains to be seen.

Penicillin at bacteriostatic concentrations inhibits ribonuclease,⁸⁴ mononucleotidase⁸⁵ and phosphatase⁸⁸ (not confirmed by a second group of in-

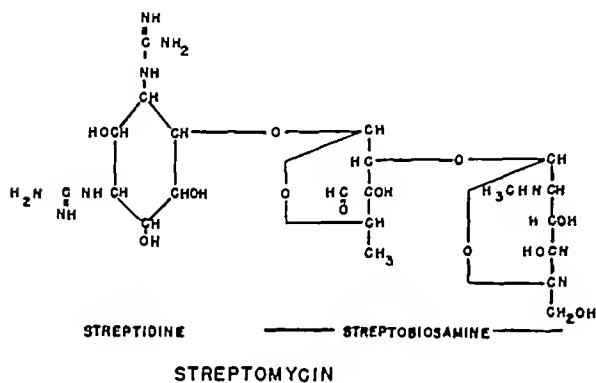

FIGURE 3 Structural Formula of Streptomycin

vestigators⁸⁷) Specific inhibition of other metabolically important enzymes has not been demonstrated.

Although a number of compounds are capable of antagonizing penicillin action,⁸⁸⁻⁸⁹ none have been shown to play a metabolic role analogous to that of PABA in the antagonism of sulfonamides. Penicillinase, an enzyme destroying the drug and produced by some bacteria,⁹⁰⁻⁹¹ is connected with one type of resistance (as mentioned below), and its elaboration by *Escherichia coli* probably explains the disappearance of a major portion of orally administered penicillin. But the enzyme clearly bears no relation to the fundamental action mechanism. Its incorporation into bacteriologic mediums to eliminate the penicillin present in body fluids taken for culture has become routine.⁹²

A remarkable series of studies by Gale and his collaborators⁹³ has revealed an entirely new and fascinating aspect of the problem of mechanism of action. They have shown that gram-positive but not gram-negative organisms are capable of actively taking up and concentrating free glutamic acid and lysine from the environment, and that this process is mediated by components of the cell

wall.⁹⁴⁻⁹⁵ The sharp distinction between the gram-positive and gram-negative groups is probably connected with the presence or absence of the magnesium-ribonucleate complex shown to be responsible for positive gram-staining properties.⁹⁶⁻⁹⁹ Penicillin acts upon the cell wall to prevent the amino-acid uptake, but only when the cells have grown in the presence of the drug. Penicillin is without effect upon the glutamic acid uptake of respiring, nongrowing cells.¹⁰⁰ Variants becoming resistant to penicillin have been shown to assume gram-negative properties,¹⁰¹⁻¹⁰² at the same time acquiring the ability to grow and reproduce without assimilating and concentrating glutamic acid, and thus, by an alternate metabolic pathway, becoming independent of the penicillin action. Indeed, it has been shown that such resistant forms are able, like most gram-negative organisms, to synthesize a number of amino acids.¹⁰²⁻¹⁰⁴

Tyrocidine, phenol and the detergents appear to act by a simple disruption of the cell wall¹⁰⁵ (demonstrable in electron micrographs¹⁰⁵) so that glutamic acid and other soluble constituents leak out. Triphenylmethane dyes were shown to block the internal utilization of glutamic acid in resting as well as growing cells, from which it is concluded that the interference is with a phase of the amino-acid metabolism not involved in growth and protein synthesis.¹⁰⁶ One such reaction blocked by triphenylmethane dyes is the formation of glutamine through phosphorylation of glutamic acid in the presence of adenosine triphosphate (ATP).⁹³ It was quite clear that neither penicillin nor sulfathiazole interfered with this utilization of glutamic acid, even under conditions of growth.

Sulfathiazole did not prevent glutamic acid assimilation by the cell wall. In growing cells only, it did block the internal utilization of glutamic acid. This blocked metabolism, however, was quite distinct from that described above, since it involved the condensation of glutamic acid residues into peptide or protein structures.¹⁷

Streptomycin

Streptomycin owes its unique position to its preferential selectivity for gram-negative and acid-fast organisms. It is unquestionably bactericidal for growing cells,¹⁰⁷⁻¹⁰⁹ and unlike that of penicillin, the killing rate increases as the concentration is raised.¹¹⁰ Strauss¹¹¹ asserts that the drug is bactericidal even for resting cells, but at a higher threshold, this suggests a different action mechanism from penicillin, which was only effective against growing cells, but conditions have not been made sufficiently comparable to settle this point unequivocally. The same investigator, and others,¹⁰⁹⁻¹¹² report morphologic abnormalities occurring at bacteriostatic levels.

To the pharmacologist it is of some interest that streptomycin is a glycoside (Fig. 3).¹¹³ Like other

demonstrated that the integrity of the cell-wall RNA of gram-positive forms is especially dependent upon reduced —SH groups^{97, 98}. Furthermore, staphylococci becoming resistant to penicillin and growing in its presence undergo two noteworthy changes: they adapt themselves to the higher oxidation-reduction potential by employing a wholly aerobic respiratory system¹⁰⁴, at the same time they become gram-negative, and acquire the ability to synthesize the amino-acids whose assimilation was formerly mediated by the cell-wall RNA^{93, 101-103}.

Evidence bearing upon the detailed mechanism of streptomycin action is still scanty. Sulfhydryl systems and RNA are both implicated by the few facts already established. Evidence that the drug can combine in a specific way with sulfhydryl compounds has already been reviewed. Streptomycin is reported to form a reversible complex with RNA, in competition with hydrogen ion and other cations¹¹⁵. The investigators suggest that although no enzyme is inhibited, RNA turnover is nevertheless disrupted, since access of enzyme to substrate is prevented. The preferential affinity of streptomycin for gram-negative forms is not clarified but may be connected with the lipopolysaccharide character of the cell wall in these species and the mycobacteria.

Obviously the facts at hand do not yet permit unification of all the clues into a single satisfactory theory. It is becoming increasingly evident, however, that antibacterial agents that have proved useful by virtue of a high chemotherapeutic ratio (in contrast to the antiseptic-disinfectant group) owe this property to a very specific interference with metabolic steps that are not shared to any important degree by host tissues. Comparative biochemistry has revealed how startlingly similar are many of the catabolic pathways and the mechanisms for elemental syntheses in all species from microorganism to man^{151, 152}. Clearly, unique modes of protein synthesis and reduplication must underlie morphologic specificity. It is not surprising, then, that drugs that are to distinguish bacterium from bacterium and parasite from host should prove to interfere in a specific fashion with the pathway of protein synthesis.

(To be continued)

to be intrinsically unstable, unless nourished by a never-ceasing flow of energy and substrates for the synthesis of protein. Interruption of the dynamic state allows irreversible denaturation of a critical system, probably nucleoprotein in nature. The denaturation of protein, in general, follows a course such that the decay of any particular molecule is unpredictable, but the *probability* that each molecule will decay in a given period can be stated. The manifest result of such a denaturation process is the logarithmic death curve, the *logarithm* of the number of surviving organisms being proportional to time.

Whether "death" produced by an antibacterial agent is reversible or permanent may be determined, at least in part, by the firmness with which the drug is bound by vital cell constituents. The classic experiments of Gegenbauer¹³⁹ showed that the loss of viability induced by mercuric chloride in cultures of *Staphylococcus aureus* was reversible by simple washing for a certain time, after which the cells could still be revived by hydrosulfide. After a critical period neither method sufficed. Reversibility by either method depended upon *both* the drug concentration and the duration of contact.

Some compounds of the antiseptic-disinfectant group (detergents, tyrocidine and chlorine) kill through an obvious lytic action on the cell wall. Others kill more subtly, at a rate suggesting direct inactivation of a single nucleoprotein molecule per cell (Rahn¹⁴⁰). These show a progressive increase in killing rate as concentration is raised, comparable to that seen in the effect of irradiation upon the reproductive mechanism. The same compounds at lower concentration stop growth and reproduction, but viability is not appreciably lost if organisms are soon enough removed from the antiseptic agent. Effects of this type are often associated with inhibition of respiration, both in growing cells and in resting cells supplied with substrate for combustion.¹⁴¹⁻¹⁴² In many compounds, therefore, antiseptic action seems to result from primary interference with energy-yielding catabolic reactions. All the effects of the antiseptic-disinfectant compounds are exerted upon nongrowing as well as growing cells.

The view that the chemotherapeutics under discussion — sulfonamides, penicillin and streptomycin — act upon the anabolic, protein-synthetic phases of metabolism is supported by two fundamental properties shared by these drugs: they exert their characteristic actions only (or most strikingly) upon growing cells, and they do not inhibit the respiration of resting organisms or the combustion of added substrates in the absence of growth. The loss of respiratory activity in growing cultures involves only the *extra* respiration associated with growth. In both respects these chemo-

therapeutics differ sharply from the antiseptic-disinfectant group.

Their intimate connection with growth and protein synthesis is further suggested by what is known of their mechanisms of action. The sulfonamides interfere with utilization of PABA in the synthesis of PGA, methionine, certain purine bases and perhaps other essential substances. Recent work with *Neurospora* mutants bears out the view that PABA may be a precursor of methionine.¹⁴³ Yet the evidence indicates that PGA is probably not an intermediate in the formation of these various compounds.³² It is possible that PABA is a common precursor in a series of parallel reactions leading to different substrates for protein synthesis. If the purine bases thus formed are incorporated into nucleoprotein, one would expect species-specific nucleic acids to antagonize the sulfonamides non-competitively. This has not yet been investigated. Gale's finding that under conditions of growth sulfathiazole prevented the condensation of glutamic acid into peptide is exactly what one would expect if PGA or other glutamyl-PABA compounds were essential substrates in the process of protein synthesis.

Recent advances in nucleoprotein research have led to the conclusion that ribonucleic acid (RNA) occupies a central role in protein synthesis. It has been suggested that "nucleic acids serve as the agents which funnel energy into the protein synthesizing mechanism."¹⁴⁴ Rapid growth is associated with a high turnover of RNA.¹⁴⁵⁻¹⁴⁶ It seems significant that penicillin, at bacteriostatic concentration, inhibits ribonuclease, mononucleotidase and phosphatase, which together are involved in the depolymerization and dephosphorylation of RNA.¹⁴⁷⁻¹⁵⁰ Furthermore, RNA is, to date, the only substrate, whose oxidation by nongrowing cells is inhibited by penicillin.⁷⁷

RNA is again involved in the specific uptake of glutamic acid by gram-positive organisms, this assimilation being inhibited by penicillin during growth. The unusual sensitivity of the gram-positive group to penicillin could be attributed to a high affinity of the drug for this cell-wall RNA system, the combination leading to a glutamic acid deficiency for growth. Gram-negative organisms, although less sensitive, are nevertheless acted upon by penicillin. It must therefore be assumed that the drug disrupts RNA turnover within both types of cell.

The observations of Pratt and Dufrenoy on the —SH to S—S shift induced by penicillin, and those of Cavallito and his co-workers on the specificity of combination of penicillin with sulfhydryl compounds, have not yet been integrated into the picture. Ribonuclease, if it is a sulfhydryl enzyme, or its substrate, RNA, may require reduced sulfhydryl groups, or may be otherwise sensitive to an increased oxidation-reduction potential. It has, in fact, been

CASE 35031

PRESENTATION OF CASE

A forty-seven-year-old unmarried woman was admitted to the hospital because of "inability to keep food down."

The patient stated that approximately one year before entry she had begun to have occasional vomiting after meals. This was attributed to nervousness. The vomiting became progressively more frequent, and eight months prior to admission it occurred once a day. She was always able to get liquid and soft foods down but could not swallow meat or other solids. When she attempted to eat solid food it "stuck" at the level of the lower end of the sternum, and in a few minutes the material was

regurgitated, unchanged in appearance. There was no nausea or hematemesis. When she was successful in swallowing a piece of solid food she experienced pain in the region of the lower sternum and even more severe pain in the back at the lower thoracic level. The pain was dull in character and lasted about two hours. Milk of magnesia sometimes eased the distress. During the following months, until the time of admission, she was forced to restrict the diet to egg-nogs, fruit juices and beef broth. She had lost 30 pounds in weight but had regained 8 pounds during the month before admission. There was considerable malaise. There was no melena, diarrhea or constipation. A roentgenogram in another hospital showed a stricture at the lower third of the esophagus, and she was subsequently referred to this hospital.

Four years before entry the patient cut her fingers on a glass. This was followed by intermittent attacks of coldness in the fingers, and the wounds became ulcerated and then gangrenous. A nerve block on the left side by injections for two weeks was carried out, but this did not help, so a bilateral cervical sympathectomy was done. After a few weeks it was considered necessary to amputate the fingers and thumb of the left hand as well as the index finger of the right hand. Later the patient's feet began to remain cold all the time, and subsequent to this a bilateral lumbar sympathectomy was performed. She had no apparent progression of the disease since that time. She had been very

and only minor dysphagia. The localized narrowing in these cases is about 4 or 5 cm above the diaphragm and constitutes an abrupt change. Esophagoscopy revealed smooth scar tissue consistent with some ulceration about the stricture. The lumen of the stricture in one case was extremely small, there was also diffuse esophagitis from the middle third of the esophagus down to the area of the constriction or to a point about 4 or 5 cm above the stomach. There was absence of normal peristalsis in the lower two thirds of the esophagus, accounting, they thought, for the impeding of swallowing fluid. The burning substernal pain they accounted for by the regurgitation of acid gastric contents through a relatively atonic cardia. They emphasized the fact that these constrictions occur at a point 5 cm above the diaphragmatic opening as a result of previous ulcerative esophagitis at that area, the latter developing because of interference with normal esophageal peristalsis as a result of sclerodermatous changes. This must, of course, be a rare cause of esophageal obstruction, but the association here with the changes that this woman had in her hands and feet makes it an interesting possibility for speculation.

Did this patient have scleroderma? It is hard for me to determine, — perhaps it would still be hard had I seen the patient, — but the impression I get is that in true Raynaud's disease the sclerodermatous changes appear late in the disease, if at all. The troubles that this woman had with ulcerative, gangrenous changes in the fingers certainly came on rather quickly. It is true that vascular manifestations may be the ones that bring the sclerodermatous patient to the physician. In one series of 40 cases about 25 per cent complained early of coldness and intermittent vasospasm,³ these phenomena becoming more and more prominent and occurring as in our patient with higher temperatures and possibly preceding skin changes by some time.

With these possibilities in mind let us ask Dr Wyman to show the films to see if the constriction bears any relation to these few cases of obstruction recorded with scleroderma.

DR F DENNETTE ADAMS Is it not usually a progressive disease? Would you not expect it to be?

DR BAKER I suppose it is, but there must be a few cases — and I shall ask Dr Lerman to comment later — in which it is largely restricted to the hands and feet, and less obviously to the face and chest, in which there is no pronounced progress.

DR EDWARD B BENEDICT I might say that the esophagus is involved in scleroderma in only a small percentage of cases. I have seen several cases, most of which showed severe esophagitis with some stricture and hemorrhage and erosion.

DR STANLEY M WYMAN The first two films are from an examination done elsewhere. They show the area of narrowing in the esophagus described in the protocol. There is a suggestion of an overhang-

ing margin on the right lateral border of the esophagus above the narrowing. We have insufficient filling of the stomach or duodenum on this film to comment on Dr Baker's question about the association of duodenal ulcer. I think it should have been looked for. There is, I believe, a definite, small, hiatus hernia. Examination done at the Eye and Ear Infirmary again shows the same diffuse narrowing with a suggestion of a small collection of barium on the right posterior aspect of the narrowed esophagus. The examination done here

FIGURE 1

shows the same constriction and a small accumulation of barium suggesting a crater at the midpoint of this narrowing, perhaps 2 cm distal to the beginning of the narrowing. Unfortunately these films are all taken in the same projection, but I cannot identify a true shelf formation, which I associate with carcinoma, and I believe that this apparent bulging of the esophagus proximal to the narrowing might be merely dilatation above the narrowing.

DR BAKER I should think this was a case in which esophagoscopy was indicated. I suppose that was done.

DR LAMAR SOUTTER It was done in the Eye and Ear Infirmary.

DR BAKER Findings at esophagoscopy would very definitely affect the decision to operate, I suppose, with resection or bouginage in mind. When I say "esophagoscopy," I mean esophagoscopy with

nervous following the operations and had not worked since that time. She lived with a nephew for a year, but at the end of this time he was married and the task of moving upset the patient considerably.

Physical examination revealed a thin, well-developed woman in no distress. There was a Grade I blowing systolic murmur heard along the sternal border. The aortic second sound was greater than the pulmonic. The lungs and abdomen were normal. The fingers and thumb of the left hand and the index finger of the right hand were missing. The skin of the remaining fingers was thick.

The temperature, pulse and respirations were normal. The blood pressure was 120 systolic, 60 diastolic.

Examination of the blood disclosed a white-cell count of 10,200. The hemoglobin was 15.3 gm. The urine sediment contained 1 or 2 white cells per high-power field. The blood nonprotein nitrogen was 17.0 mg., and the total protein 5.6 gm. per 100 cc. The prothrombin time was 15 seconds (normal, 16 seconds).

An electrocardiogram showed slight left-axis deviation.

A roentgenogram disclosed an annular defect of the distal esophagus about 5 cm. above the diaphragmatic opening (Fig 1). The actual defect measured 1 cm. in length, with rather marked shelving above. Most of the compression appeared to be on the right and posterior side of the esophagus.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR MYLES P. BAKER. I think it might be instructive in discussing this case to put ourselves in the position of the ward officer confronted with this history and physical examination and discuss the diagnostic possibilities with just this verbal report of the x-ray examination in mind and then view the films later. Doubtless the nature of the deformity disclosed by x-ray study is going to be important diagnostically.

We are dealing with a middle-aged woman who developed dysphagia, regurgitation without nausea and substernal pain after swallowing solids for a year, coming on three years after symptoms, either of Raynaud's disease involving the hands and feet or scleroderma with Raynaud's phenomenon, the so-called acroscleroderma, had appeared. The diagnostic possibilities seem to me, first, that she had carcinoma of the esophagus, causing the filling defect in the lower third of the esophagus. It must be considered regardless of any other associated abnormalities found on physical examination. The symptoms that the woman complained of are in keeping with that diagnosis — namely, early minor dysphagia, substernal pain, reported as present in 75 per cent of cases of carcinoma of the esophagus

and frequently radiating to the back, and regurgitation of food, mentioned by Vinson¹ as not being particularly common with cancer, and by others as being present in some 20 to 65 per cent of cases. Weight loss, marked in this case, is characteristic of the disease. The weight loss in this case was not progressive. The absence of anemia or marked hypoproteinemia might be looked on as a favorable sign indicating that one was not dealing with carcinoma of the esophagus. There must be cases of carcinoma, however, that present no anemia in which the patients look surprisingly well nourished.

Another possibility is benign stricture of the esophagus. The position of the obstruction here is 5 cm. above the diaphragmatic opening and is probably compatible with benign stricture of the esophagus and certainly much more so than with the entity cardiospasm, which is due to obstruction in the interdiaphragmatic segment of the esophagus — lower down than we have any evidence of in this case.

What basis have we in the history for any cause of benign stricture of the esophagus? There is no mention of chemical trauma, no antecedent acute infection and, indeed, nothing of history compatible with recurrent peptic esophageal ulcer, nor have we an x-ray report of the presence of diaphragmatic hernia or short esophagus, which are recorded as being so frequently associated with demonstrable peptic ulcer of the esophagus. We have no comment about the presence of a duodenal deformity such as a man might have who had had an active duodenal ulcer in the past — a finding frequently observed in patients with peptic ulcer of the esophagus.

We do have, however, this unique and, in the protocol, emphasized association of esophageal stricture with a past history of serious disease affecting the hands and feet, the precise diagnosis of which is a little difficult to be certain about on the data presented here. It is well known that real disturbance in esophageal function may be an early symptom in scleroderma, a disease that is certainly a rarity to me and, with esophageal symptoms, a combination that I personally have never seen. I found a reference to this association of esophageal troubles and scleroderma in an article by Lindsay, Templeton and Rothman.² They report 5 cases with varying degrees of esophageal stenosis in 3. Their first patient had initial symptoms of dysphagia due to benign esophageal stricture for one and a half years before developments similar to Raynaud's disease made their appearance. The third patient developed substernal pain one hour after eating food, with some relief on taking alkalies — as our patient had — followed about six months later by numbness and coldness of the fingers, with benign stricture of the upper border of the phrenic ampulla, as did their second patient, with scleroderma of two and a half years' standing,

and only minor dysphagia. The localized narrowing in these cases is about 4 or 5 cm above the diaphragm and constitutes an abrupt change. Esophagoscopy revealed smooth scar tissue consistent with some ulceration about the stricture. The lumen of the stricture in one case was extremely small, there was also diffuse esophagitis from the middle third of the esophagus down to the area of the constriction or to a point about 4 or 5 cm above the stomach. There was absence of normal peristalsis in the lower two thirds of the esophagus, accounting, they thought, for the impeding of swallowing fluid. The burning substernal pain they accounted for by the regurgitation of acid gastric contents through a relatively atonic cardia. They emphasized the fact that these constrictions occur at a point 5 cm above the diaphragmatic opening as a result of previous ulcerative esophagitis at that area, the latter developing because of interference with normal esophageal peristalsis as a result of sclerodermatous changes. This must, of course, be a rare cause of esophageal obstruction, but the association here with the changes that this woman had in her hands and feet makes it an interesting possibility for speculation.

Did this patient have scleroderma? It is hard for me to determine, — perhaps it would still be hard had I seen the patient, — but the impression I get is that in true Raynaud's disease the sclerodermatous changes appear late in the disease, if at all. disease but also associated with various other conditions such as uremia

DR WYMAN Did this woman have a duodenal ulcer?

DR MALLORY None was found

DR BAKER This was more than esophageal ulcer and spasm — definite stricture?

DR MALLORY Definite ulceration with marked scarring and narrowing of the lumen

DR KING Is it your impression that most of them are lower than this?

DR MALLORY Yes, this was relatively high

CASE 35032

PRESENTATION OF CASE

A thirty-nine-year-old woman was admitted to the hospital because of easy fatigability, pain in the left anterior chest and the presence of an abdominal mass

One year before admission the patient first noted a sharp pain in the left anterior chest. The pain radiated across the left anterior chest to the axillary line, up into the axilla and down the inner aspect of the left arm to the wrist. At times the fingers became numb in association with this pain. About a year before admission she developed sharp, crampy, pelvic pain. There was no associated vomiting or bowel irregularity. The menstrual periods became irregular, and the amount of flow decreased. A hysterectomy for fibroids was done nine months before admission, with relief of the pelvic pain. No pelvic masses, except for the fibroids, were seen at operation. An appendectomy and right oophorectomy had been done nine years before admission.

Physical examination revealed a left-lower-quadrant mass. The cul-de-sac was empty, and the mass, approximately 6 cm in diameter, rode up out of the pelvis. The heart was not enlarged, and the apical rate was regular.

The blood pressure was 160 systolic, 95 diastolic. Examination of the urine and blood was within normal limits. A Graham test was negative. A barium enema was reported as showing no evidence of intrinsic involvement of the colon, but the colon was displaced by an extrinsic mass (Fig 1).

On the fifth hospital day a laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR GORDON A DONALDSON I doubt very much whether the first perusal of this history has left any of you colder than it did me. On looking at it further, however, it is possible to summarize some of the salient points and find that approximately a third of the history can be accepted as a definite fact — namely, that the patient had a hysterectomy and that the right tube and ovary had been removed earlier. My only comment about this portion of the history is that we would like to know why the right ovary was removed nine years earlier. What was

FIGURE 1

the lesion? I am a little suspicious of a fibroid causing sharp, crampy, pelvic pain and wonder if something was overlooked in the pelvis nine months before at the time of laparotomy. Also, I would call attention to the cautious statement "no pelvic masses, except for the fibroids" were noted at this time. I wonder how much search was made for the left ovary.

So we are left with a thirty-nine-year-old woman with pain in the upper part of the torso and a mass in the lower part of the torso, both on the left side. It is always dangerous to make two diagnoses at these conferences, but unless the x-ray film can help us considerably I think we may be forced to

biopsy properly taken from the area of constriction. Both the history and the x-ray examination, as Dr Benedict has pointed out, are inconclusive in obstructive lesions of the esophagus, and only by direct observation and by study of biopsy material can one be sure of what one is dealing with and of a proper decision about procedure.

As far as the diagnosis is concerned, in this particular case I would favor that of benign stricture rather than that of carcinoma of the esophagus. Whether it has any relation to the associated peripheral vascular disease or true acroscleroderma is worthy of mention.

DR DONALD S KING Where does the so-called string sign come into a lesion like this, Dr Wyman?

DR WYMAN I think the lesion is too high for it.

DR JACOB LERMAN Patients with Raynaud's scleroderma syndrome certainly show many bizarre manifestations. The course is variable. Sometimes the sclerodermatous lesions dominate, and sometimes the Raynaud symptoms. In answer to Dr Adams's question we have seen patients who have progressed so far and then remain stationary for years.

Another point worth bringing out is that the sclerotic process that is present in the extremities is a universal process, and similar changes are seen in the myocardium and other organs. Some of these patients develop malnutrition as a result of the constant vomiting and with it an esophagitis on top of the esophageal fibrotic process, so that the picture on x-ray examination will be altered from time to time. The x-ray film shown is consistent with benign stricture complicated by esophagitis.

DR BENEDICT I do not know the diagnosis or treatment in this case, but I assume that the operation performed was esophagoscopy with biopsy, since that is the only sure way to differentiate benign stricture from carcinoma. The importance of taking a biopsy cannot be overemphasized because the treatment of benign stricture is bouginage, whereas the treatment of carcinoma is resection.

DR SOUTTER This woman was just as much a problem for us as she was for Dr Baker today. On the ward we did not believe she had clinical evidence of scleroderma. We discussed that diagnostic point and concluded that she did not have scleroderma of the esophagus. The report from the esophagoscopist and the roentgenologist was that carcinoma could not be ruled out. The esophagoscopist did not see anything more than the upper limit of the lesion. He was not able to obtain an adequate biopsy. We thought that we would have to explore this woman's esophagus because of the possibility of carcinoma. Furthermore, in many people who have benign strictures there is more dilatation of the esophagus above the stricture than there is in these films.

In the operating room we found the esophagus thickened over a small area at about 8 cm above

the cardia. It was a dense type of thickening, and we could not decide on palpation whether it was some benign lesion in the wall of the esophagus extending through the muscularis or whether it was a carcinoma. A few years ago in a patient who presented a problem of this nature we opened the esophagus with a longitudinal incision, thinking we were probably dealing with a benign lesion but found a malignant one. Although that tumor was resected, we had recurrence in the chest cavity, which we thought was due to spreading the disease by cutting into the tumor. Therefore, in this case we believed that opening the esophagus in the presence of carcinoma might lead to metastases. So we could see no alternative but to resect the lesion.

DR BENEDICT Dr Soutter seems to be arguing that the fact that this esophagus was not dilated is in favor of carcinoma. I do not agree. It is true that in long-standing achylasia (cardiospasm) the esophagus becomes dilated, but not in benign stricture.

CLINICAL DIAGNOSIS

Carcinoma of lower esophagus

DR BAKER'S DIAGNOSIS

Benign stricture of esophagus, unknown etiology

ANATOMICAL DIAGNOSIS

Peptic ulcer of esophagus, with stricture formation

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY The resected specimen showed a benign ulceration of the esophagus that had the characteristic histology of peptic ulcer. As is customary in such cases we found several islands of gastric mucosa in the esophagus. The wall of the esophagus beneath the area of ulceration was scarred and thickened, but we thought that that could be entirely explained as a secondary reaction to the ulceration of the mucosa and did not indicate a preceding sclerosis of the sclerodermatous type.

Following operation the patient developed progressive difficulties, the anastomosis failed to heal, and empyema developed. She died about one week postoperatively. At autopsy the remainder of the esophagus was free from any sclerotic changes. Sections from one of the nongangrenous fingertips showed endarteritic changes, nonspecific in character, such as are frequently seen in Raynaud's disease. There was nothing on which we could make a histologic diagnosis of scleroderma.

The only other finding of some histologic interest was marked cystic dilatation of the pancreatic glands, a lesion that I saw with some frequency in the Army and have seen very rarely in civilian life. In this case I have no explanation for it. I have seen it in people very severely ill for a week or more before they die, frequently in cases of infectious

DR ADAMS Some time ago she was given an estrogen preparation for a while. It was stopped before hysterectomy. After that she received none. The note I made before she came to the hospital was that she had a mass up to the umbilicus.

DR MALLORY The question that I would have liked to ask at this point is whether the sponge count was certainly correct at the last operation.

DR ADAMS I did not ask that one.

DR WYLAND F. LEADBETTER Is the x-ray compatible with an anterior meningocele?

DR WYMAN There is no evidence of anything definite in the spine. It is a little unlikely to have anterior meningocele so low to the left of the midline, and it looks like two masses or a lobulated mass.

DR JOE V. MEIGS I have now seen three anterior meningoceles — two retroperitoneal at the midline, and the third on the left side. One could feel them fairly well.

DR MALLORY Are there any suggestions from the x-ray point of view?

DR WYMAN This is a homogeneous soft-tissue density that may be lobulated or may be multiple.

DR DONALDSON It is very unlikely for a lymphoma to present such a picture. I will stick to my diagnosis of endometrioma.

CLINICAL DIAGNOSIS

Ovarian cyst

DR DONALDSON'S DIAGNOSIS

Endometrioma

ANATOMICAL DIAGNOSIS

Hematoma of broad ligament and sigmoid mesentery

PATHOLOGICAL DISCUSSION

DR MALLORY Dr. Parsons, will you take up the story?

DR LANGDON PARSONS The chest pain is obviously a red herring, and I did not have to con-

sider that because Dr. Adams told me to let that alone. This mass was not in the pelvis, but rode up above it to the level of the umbilicus. Aside from the history the strongest point against ovarian cyst was that at pelvic examination the mass did not descend at any point into the pelvis. At operation we were confronted with a voluminous, blue-domed cyst lying between the broad ligament and the leaves of the sigmoid. At first I thought it was an ovarian cyst, but I soon found that I could not get around it and that it was retroperitoneal. It was actually pretty much on a level with the pole of the kidney, and the majority of it lay within the leaves of the sigmoid mesentery. I found a normal left ovary. As far as I can reconstruct this thing I believe that at the last operation the stump of the retained ovary was buried between the leaves of the broad ligament. Hemorrhage followed, and the hematoma gradually spread from the broad ligament into the sigmoid mesentery. We evacuated the hematoma, which drained about two liters of bloody fluid, and took a few biopsy specimens from the wall of the cavity.

DR MALLORY Our fragments from the wall showed only granulation tissue, organizing blood clot and hemosiderin, all evidences of old hemorrhage. We looked for endometriosis and found no evidence of it.

DR PARSONS We have talked about the rarity of cysts of the retained ovary. I do not think that we see many.

DR ADAMS Did you say that you found the left ovary?

DR PARSONS A normal left ovary.

DR MEIGS We do not see many cysts in retained ovaries — in fact, extraordinarily few. We have only seen one or two in the Vincent Memorial, although we leave an ovary in whenever possible in women who have not reached the menopause.

DR F DENNETTE ADAMS May I interrupt at this point to answer some of these questions When the appendix was taken out the ovary was said to have a cyst in it and was also removed Both operations were done in another city The story I obtained on the second operation was that the uterus was deformed, not by fibroid tumors, but by some congenital abnormality The left ovary was said to have been removed with the uterus Both operations were done by a capable surgeon in another city

DR DONALDSON Can we accept that as a fact?

DR ADAMS All I can say is that the surgeon who did the operation is highly capable and that the uterus and the left ovary were reported to me, although not by the surgeon, to have been taken out

DR DONALDSON May we see the x-ray films?

DR STANLEY M WYMAN The gall bladder is normal The plain film of the abdomen shows a soft-tissue fullness in the pelvis, slightly more to the left, and rising up into the abdomen, overlying the sacrum It appears larger on the film than it seems from the description of the physical examination One cannot be sure if this is a lobular mass or includes two or more separate masses The barium-enema examination shows the sigmoid to be displaced upward, apparently by a mass in the true pelvis, with a second mass or possibly a lobule of the mass rising above it at this point The bones appear normal as far as I can see on these films The masses are homogeneous and show no calcification

DR DONALDSON This is a huge mass that developed in nine months, and I still believe, from its position in the x-ray film, that it must have been related to the base of the broad ligament, perhaps the ovarian pedicle Was the hysterectomy total?

DR ADAMS I think it was I could not feel the cervix when I did a pelvic examination — for what that may be worth

DR DONALDSON We can eliminate the colon because of the lack of history and the negative barium enema Prolapse of an organ high in the abdomen such as the stomach or kidney or omental tumor is very unlikely I still believe that our information concerning the left ovary is not completely black and white, and we should still consider the possibility of disease in the left ovary or remnant of the left ovary As a matter of fact, I am really thrown off guard by the added information that the left ovary was absent I had a good story worked out for it One was a fibroma, the Meigs syndrome, an unlikely possibility, however, because of the site of the chest pain The tumor was described as 6 cm long, which is just about right for a fibroma This tumor is much larger than that, and the possibility of carcinoma with metastasis to the lungs came to mind, but the patient seemed to be in too good shape to have had a metas-

tatic lesion in the lung for a full year I suppose we ought to consider a residual, simple cyst of the left ovary

Finally, an endometrioma with pulmonary metastases is something that has been reported I glanced through the literature and found that there have been pulmonary metastases from endometriomas of the ovary This picture is consistent with that, but perhaps, again, the size of the tumor throws out that diagnosis An endometrioma 6 cm in diameter could have developed over the course of a year in a thirty-nine-year-old woman, and it is probable that she could have had symptoms from a properly placed metastasis in the left lung

DR ADAMS May I interrupt again because I believe that the history is not fair to Dr Donaldson This pain in the chest had existed, to my knowledge, for two and a half years The patient described what sounded like anginal pain, but I do not believe she actually had angina The pain in the chest existed long before any of the pelvic symptoms appeared

DR DONALDSON I wondered if it was cardiac pain She was slightly hypertensive, perhaps menopausal

DR ADAMS That was the only observation of high blood pressure I always found her pressure normal in my office

DR DONALDSON Because of the lack of any history of angina and the presence of numbness in the fingers it is an unlikely possibility

The possibility of a cervical rib or tight anterior scalene muscle as a cause of such pain might be considered It is unusual for such a syndrome to produce pain in the anterior chest wall itself We ought to consider perhaps a slowly growing lesion of the chest wall or of the lung, such as a Pancoast tumor with metastases to the pelvic organs Again, the patient was too young and apparently too well, and the history too long I think it would be unusual for this woman to have such a lesion I believed that endometrioma with metastases to the lung was the best bet Against this is the fact that the tumor was so large, but I suspect that an endometrioma could have developed to this size in nine months' time

DR JOHN McL MORRIS Is there a chest film?

DR ADAMS It was normal How recently it was done, I do not know

DR TRACY B MALLORY Are there any other suggestions?

DR GRANTLEY W TAYLOR A mass 6 cm in diameter riding out of the pelvis would not push the transverse colon up I wonder if Dr Adams has a note on that

DR ADAMS I felt it, so it must have been pretty big

A PHYSICIAN Was she given estrogen for the menopause?

to do their share, and promptly, in implementing the program that is being planned

There is today one vital consideration for physicians to remember. They must work in harmony if they are to achieve through their own initiative those things that others believe can be achieved better by methods of compulsion

HEMODYNAMICS IN THE LUNGS

UNTIL comparatively recently, knowledge of abnormal changes in the blood pressure in the pulmonary circuit has been largely speculative. It is now possible to make direct measurements of the blood pressure in the arterial portion of the pulmonary circuit and to relate abnormalities in such pressures to clinical and post-mortem findings. The full implications of such studies, now being carried out in a number of laboratories, are likely to be profound.

Pulmonary hypertension has been recognized as a rather indefinite clinical entity for many years. Pulmonary vascular sclerosis has been familiar to pathologists since the middle of the last century. One of the most illuminating, if somewhat neglected, monographs on the latter topic is that by Ljungdahl,¹ which appeared in 1915. In this work, sclerotic changes in the pulmonary vessels were shown to be relatively frequent in mitral stenosis and to occur in certain congenital cardiac lesions, notably patent ductus arteriosus, in some cases of pulmonary emphysema and in the obscure and rare entity known as primary pulmonary vascular sclerosis. It is also likely that such vascular disease occurs in some cases of cardiac decompensation on a hypertensive or arteriosclerotic basis.

With the modern technics now available it is possible to study in the living patient the alterations in pulmonary arterial blood pressure that have, largely by implication, been said to accompany pulmonary vascular sclerosis. Of much greater importance is the likelihood that, by establishing the presence of pulmonary arterial hypertension, the investigator can predict the presence of vascular changes within the lung. Such information not only may prove to be of great prognostic value but also may be of considerable value to the surgeon when the proposed operations for mitral stenosis become a practical matter.² The

surgeon may logically expect to obtain his best results in patients who have not developed pulmonary vascular sclerosis and therefore to urge operation relatively soon after the valvular lesion is discovered. Similarly, in cases of patent ductus arteriosus, complete relief from symptoms after ligation should probably not be predicted if the pulmonary arterial pressures and clinical symptoms indicate that advanced pulmonary vascular sclerosis is present.

The new technic has already thrown considerable light on some of the many perplexing questions having to do with cardiac failure and the pathogenesis of such related phenomena as pulmonary edema and paroxysmal nocturnal dyspnea. Before these events can be completely understood some means of measuring pressures in the left atrium and in the venous portion of the pulmonary circuit must be developed. Even without such means etiologic understanding and genuinely rational therapy are being furthered by those engaged in studying pulmonary arterial pressures.

The entire field is one of great promise and is still another example of the benefit that accrues to medical science when investigators avail themselves of sound existing knowledge and develop imaginative technics, whether morphologic or functional.¹ It is also another example of a basic research endeavor that has, in a relatively short time, proved to possess great practical significance.

FISH OR CUT BAIT

THE medical profession, which has made such impressive advances along clinical and scientific lines, must decide, and shortly, whether it has also the ability and the interest to maintain and control and modernize its own time-honored standards of service.

To do this it must sacrifice certain of its cherished beliefs of other days. It must to some extent submerge, for the sake of a wider distribution of its benefits, that personal independence and freedom of action so characteristic of the private practitioner of medicine. It must freely acknowledge that any form of voluntary health insurance that offers a decent standard of medical care to all economic and social groups is more effective than the individually bestowed charity for which it has been so conspicuous, and that has always been so freely given

It must realize that it is functioning in a world in social revolution, and that slow evolutionary processes of change are not adequate to bring it up to the times and keep it abreast of them. It must understand that the only apparent alternative to such a remodeling of its methods is capture and eventual domination by other forces that, lofty as their motives may be, have yet but a limited understanding of the traditions, the ideals and the technics that they seek to control.

The profession of medicine must, and must now, come fully awake to its responsibilities, to the dangers that threaten it — and to its own strength. It must make up in a few brief months for years lost in the cultivation of its public relations. It must teach a forgetful public what that public owes it, it must acknowledge openly what it owes the public, and present its plan of payment. It must acknowledge its inertia, its blunders and its former indifference to public opinion, and wash them out.

It must show its receptiveness to new ideas and its ability to discuss their common problems with all agencies that are honestly seeking the same goal of service.

To do these things now and effectively requires money — not a war chest or a slush fund, as it has been termed by the chief protagonist of compulsory insurance, who has the resources of a federal agency with which to promulgate his own ideas — but an educational fund to put clearly before the public the accomplishments and the capacities and the honest intentions of a free but united profession.

The proposed assessment is necessary in order that the American Medical Association, *representing the medical profession of the country*, may put its relations with the public on a sound basis. If the assessment is paid with some scolding and a lecture, then let it in that way be given, for criticism may serve two purposes — to relieve the critic and, so far as it is constructive, to guide the recipient. The important thing is for every member of the profession now to rally to the support of his ancient and honorable calling, to show his pride in it and to contribute to the maintenance of its standards and its prestige. The secretary of the Massachusetts Medical Society, acting in this instance only as an agent of the American Medical Association, is taking the steps necessary to collect the assessment for the parent organization. The physicians of Massachusetts are urged

to do their share, and promptly, in implementing the program that is being planned

There is today one vital consideration for physicians to remember. They must work in harmony if they are to achieve through their own initiative those things that others believe can be achieved better by methods of compulsion

CARE OF THE MENTALLY ILL

THE twenty-ninth Annual Report of the Massachusetts Department of Mental Health was presented as required by law to the Governor and Council on November 3, 1948, by Dr. Clifton T. Perkins, commissioner of mental health of the Commonwealth.

A few extracts from this report, which points out the deplorable conditions that exist for the care and treatment of mentally ill patients in the Commonwealth, are pertinent.

One of the greatest problems in the field of mental health, according to Dr. Perkins, is the absence of any broadly based, mature application of an in-

formed public opinion to serve a state department as an intelligent, critical and effective supporter as the situation may from time to time demand. This statement of Dr Perkins is particularly applicable to the members of the medical profession, probably few of whom are well informed about the conditions as they exist.

In general, the report continues, the Department is responsible for providing for the efficient, economical and humane management of the state hospitals and may establish by-laws and regulations for the government of those hospitals, of which there are sixteen, caring for approximately 30,000 patients. It is pertinent also to realize that 95 out of every 100 persons in the Commonwealth who need mental hospitalization must be cared for in the state hospitals because they cannot afford the price of private facilities. For better or worse, the State has a practical monopoly — the fate of the mentally sick citizen is literally in its hands.

The report furthermore shows clearly that the responsibilities mentioned are not being adequately met. The Commissioner points out that World War II materially reduced over-all medical standards in the state program because of the inability of the Commonwealth to compete in the manpower crisis, and the inexorable demands of the armed forces. Recovery has not yet been made from that reduction of standards.

Basically, there are "not enough well trained doctors or nurses or occupational therapists or other personnel indispensable to the proper bedside care of patients and execution of therapeutic programs either within the hospital or the clinics."

The quotas allowed for the work by the state are less than the standards deemed minimum by nation-wide agencies in the field of mental health, but even these quotas are not met. In the quota allowed for physicians there was as of September, 1948, a vacancy of 25 1/4 per cent, in the ward services the vacancies amounted to 30 8/8 per cent.

The loss of every trained doctor, according to the report, entails years of training for the physician who is to replace him.

Mere swapping of holders of M.D. degrees does not make up for the loss. The doctors we have lost almost without exception have gone where they can get more cash, have less restrictions in regulating their lives, where more adequate personnel is available in the ancillary fields to help them in their work.

Doctors, like other scientific men, will take just so much pushing around financially and otherwise. Compared with the competition, the Commonwealth has failed to realize this fully.

The Commissioner in this statement puts his finger on the fact that to provide a satisfactory medical service the pay must be on a competitive basis, but there must be, in addition, a proper atmosphere in which a physician can flourish. He further points out that teaching and training activities constitute one of the best ways of maintaining an active and alert staff and emphasizes the importance of research as an outlet for an active staff.

Unless the conditions for the care and treatment of the *mentally ill* patients are promptly improved, there can only occur a demoralization that is bad for both the community and the medical men who make up a part of the community. It appears that the physicians of the Commonwealth, individually and through their medical societies, — state, district and local, — would be well advised to inform themselves of the conditions as they exist and take an active part in their improvement.

HISTORY OF PHARMACY

THE first Pan-American Congress of Pharmacy, meeting in Havana late in 1948, gave official recognition to the American Institute of the History of Pharmacy at the University of Wisconsin. The Institute was named "as the center of the endeavor in the history of pharmacy in America."

Through a more formal representation of Latin American countries in the Institute, with a trustee in each of them, it is hoped that investigations into the history of pharmacy will be broadened and a series of monographs may be published on the history of pharmacy in all the countries of this hemisphere. Among the more practical aspects of the congress was the discussion concerning unification of official drug standards and the publication of a Pan-American pharmacopeia.

Practicing, during the development and progress of his ancient profession, similar forms of magic and mystery, the pharmacist finally emerged as a true scientist at about the same time as did his co-partner in the investigation of drugs, the physician. Modern medicine owes much to this continuing partnership.

CORRESPONDENCE

REGARDING THE AIA ASSESSMENT

To the Editor You may have seen the recent press statement that those who control policy in the American Medical Association have voted to assess all members \$25 each. And that the proceeds (\$3,500,000) are to be "spent on a campaign of 'education' to tell people the advantages of the 'American system' of medical care." There is no evidence that this sum will be used in an unbiased search for facts or in the promotion of impartial discussion. On the contrary, judging by past editorials in the *Journal of the American Medical Association*, the actual purpose is to influence opinion in one direction by presenting one side of a controversial issue.

This is not education, it is propaganda. Should American doctors be subjected to such an extraordinary tax without their consent? Even if such action by the American Medical Association officials should be pronounced legal I believe that it is unethical.

Therefore, I suggest that the *New England Journal of Medicine* and the Massachusetts Medical Society openly oppose any such tax until a referendum has been held.

It would be possible for a voting slip to be inserted in each copy of the *Journal of the American Medical Association* for one issue after January 1. Until some such referendum is held I have no intention of paying this tax.

HENRY S. FORBES, MD

Milton, Massachusetts

To the Editor The many inquiries concerning the recent decision of the House of Delegates of the American Medical Association to assess each member \$25.00 indicate a need for clarification of many aspects of this charge. Very little information is provided by the editorial in the *Journal of the American Medical Association*, which announces the decision and states that the purpose is "to provide a fund adequate for meeting the proposal of the present administration and particularly the present Federal Security Administrator to nationalize the services of the medical profession through the enactment of a compulsory sickness insurance act covering every person in the United States."

Before paying the assessment many doctors want to know (indeed should know, if they are to act as intelligent physicians and citizens) a few simple things about the assessment: Is the money raised to be spent by the county medical societies, by the state medical societies or by the American Medical Association? Is it to be spent merely in opposing by reiterating, as Mr. Baruch says, "what not to do" or by proposing constructive action? If the constructive action pertains to voluntary insurance will endorsement of voluntary plans be limited to Blue Cross Hospitalization and Blue Shield Medical Service or will well organized plans such as The Health Insurance Plan of New York City, the Permanente Foundation Health Services of California and the Lahor Health Institute of St. Louis be encouraged? Will opposition to General Hawley's proposals concerning Blue Cross and Blue Shield continue?

Many doctors, particularly the younger members who may have little vested interest in current medical practice and but little professional or other income want to know if this assessment is compulsory in the sense of losing membership or good standing in the county and state medical societies and hence the American Medical Association, or even of receiving prejudiced consideration as applicants to or members of hospital staffs.

That young physicians can fear such a possibility is not only a serious reflection upon the ethics of the profession but also a serious threat to the future of the American Medical Association. Up to now membership in a county and state medical society and the American Medical Association has frequently been used as a qualifying requirement for positions on many hospital staffs or other professional privileges. If membership becomes contingent upon paying an assessment that more than doubles the income of the American Medical Association and is to be used to oppose legislation endorsed by the President of the United States and the majority party of Congress a major purpose of the American Medical Association becomes not only political but also highly controversial. Under such circumstances if political rather than professional considerations determine membership, can the American Medical Association continue some

of its important roles? For example, can membership any longer carry a connotation of professional qualification that places nonmembers at a disadvantage?

Compared to jeopardizing such traditional functions the question of what will happen to the American Medical Association's tax status as an educational and nonpolitical organization is of minor concern. In this connection one wonders why the House of Delegates decided to have the American Medical Association raise this money itself rather than continue having it done by the National Physicians Committee, which already ranks as one of the top lobbying organizations in the country.

Many of these questions must have been debated by the House of Delegates in arriving at its decision to make the assessment. That the debate was held in executive session, therefore, seems unfortunate for it is unlikely that members of the House would have said things that the public should not hear, and its answers to many questions should be enlightening. If the debate provides them, it would appear deserving of publication. If not provision for tolerant discussion and considered debate seems essential to a democratic professional behavior to an enlightened professional opinion and to a respect for that opinion by the public.

Ironically should discussion be suppressed and physicians pay the assessment under compulsion, would not the American Medical Association be practicing what it professes to abhor—namely, domination by a federal or national body of state and county units that constitutionally are autonomous?

I trust that the Massachusetts Medical Society will deal with this matter according to its traditionally New England democratic way.

ALLAN M. BUTLER, MD

Massachusetts General Hospital
Boston

To the Editor The people's mandate, handed down at the polls on November 2, 1948, is frequently interpreted as requiring federal participation in the provision of less expensive and more extensive medical care for the American people. Whatever physicians may have believed before November 2 the attitude of the public toward health legislation should be reasonably plain at present. Whether the entry of the federal Government into the field of medical care on a large scale is wise or foolish, the possibility of it is nearer than ever before. Blind opposition to this possibility is an invitation to disaster. Neither the medical profession nor any other professional or occupational group can successfully defy the majority rule in the United States as now constituted. For the profession to attempt such defiance would be tragic indeed, it would inevitably mean the lowering of organized medicine in the eyes of the public to the position of an economic pressure group, surely an ignominious decline from a position deserving and receiving the faith and trust of layman and physician alike.

The Government's plans to solve the nation's medical economic problems have been published for all to see. Mr. Oscar Ewing the federal security administrator, and his advisers have produced a plan that they believe will meet our needs. The plan includes provision for compulsory health insurance a feature that may well be neither desirable nor necessary at the present time. Be that as it may no reasonable person can doubt that Mr. Ewing and his colleagues have made a serious effort to master an enormously complex socioeconomic problem and to provide effective remedies acceptable to the nation as a whole. It is ridiculous to regard the plan as the instrument of Leninism, and it is naïve to believe that, even if made into law without a change, it would communize American medical practice. It is just as ridiculous to accept it as the perfect answer to the nation's needs or to assume that it must pass the Congress unchanged and unamended. Meek acquiescence on the part of the profession to the bill as it now stands is unthinkable.

If the profession must accept the near-reality of federal participation in the provision of medical care what, then, should be its attitude toward the Ewing Plan? A specific, point-by-point answer is urgent and for it to be effective it must concern itself primarily with improved standards of medical care and secondarily, if at all with the status of the physician. The tremendous uproar over medical care in this country and the objections of the medical profession to plans and planners have centered too much on the prestige, the

dignity and the rights of the physician. Improvement of medical standards as a primary goal has been sadly obscured by both groups. The Ewing Plan is an economic plan designed to provide abundant, low-priced medical care to everyone, but not concerning itself specifically with improving the standards of medical practice. Similarly, the profession's objections to the plan have been based largely on the protection of free enterprise and the status quo, either by direct statement or by implication, although medical standards have occasionally been dragged in to underscore an economic point. The unfortunate tendency of some professional groups to concern themselves primarily with financial matters led one highly respected medical spokesman, H. J. Morgan, in an article entitled "Professio" (*Ann Int Med* 32:887-891, 1948) to say:

One of our so-called professional organizations has emphasized economics and the material aspects of medical practice so vociferously and forcefully as to lead some of the people and some of the people's representatives in government to consider it a business or trade organization. A Federal Court decision revealed in no uncertain terms that Medicine in the United States, in this instance, forfeited its professional status before the law. It appears that by word and deed we interpreted ourselves to the people and the courts as tradesmen.

It is still not too late to do our own house cleaning. An effective plan embodying federal participation, must be evolved by the profession itself, and it must be one that will inspire the confidence instead of the distrust of the public. The plans offered by organized medicine to date have been defensive plans, designed to change the *status quo* as little as possible. An entirely new approach is essential. It must be based primarily on the intent to distribute high-grade medical care as widely as possible. There must be no reluctance to alter the *status quo* merely because of fear of change. The profession must set up its considered plan for the ideal system of medical care. No stop-gap compromise will suffice as a master plan. From its plan for the ideal system, the profession and other medical planners can then proceed to arrange the details, economic and otherwise, to suit the circumstances. An imaginative and courageous approach of this sort will stand in sharp contrast to the grumbling and lusterless schemes currently being brought forward by the profession to counter the popular, but usually defective, offerings of Government planners.

The perfect solution has not yet been presented. It is the medical profession itself that must evolve and present it. There should be no more jousting at windmills. The profession should brutally scrutinize its own conscience, examine the facts and set the pace, not only for the political planners but also for itself. By audacious and sober action, it can regain its position as the profession of integrity and unassailable standards. If its actions continue to be motivated merely by blind resistance to change it will reap catastrophe, the full extent of which no man can now foresee.

CARLETON B. CHAPMAN, M.D.

Minneapolis, Minnesota

To the Editor: Certain recent inquiries and comments concerning the action of the American Medical Association in assessing its members twenty-five dollars are disturbing. Hypercritical comments from those committed to compulsory national health insurance have validity commensurate with their underlying logic. Adverse criticism based on lack of information is entirely another matter.

At the annual meeting of the American Medical Association in Chicago in June the House of Delegates voted to raise the levying level through dues or assessment to twenty-five dollars. The extensive activities of the parent organization have been heretofore conducted without dues or assessment other than the amount paid for subscription to the *Journal of the American Medical Association*. At the recent interim session conducted in St. Louis the full House of Delegates for reasons sufficient to our delegates unanimously voted the maximum assessment.

There may well be valid criticism of the existing structure of our medical house. Minority opinion may not be adequately represented. But certain basic facts are valid. The House of Delegates of the American Medical Association

is composed of state-society members elected on a proportional basis. When we castigate the American Medical Association in public we are castigating ourselves. When the house is on fire is no time for a jurisdictional dispute over who should man the hose.

The St. Louis assessment because of its urgency could not apparently be discussed in advance of the meeting. The response to the assessment as voted has not been good in the press generally and has been universally poor among the more vocal proponents of federal planning.

Most of us need information on the basic facts at issue. An extensive educational campaign for physicians and for the public is immediately forthcoming. A few million dollars for the job to be done is inconsequential in view of its importance.

Final judgment on the assessment should be withheld until the reasons that produced a unanimous vote of the House of Delegates are made known to all of us. This information is on the way. In the meantime, one aspect of this issue is clear. Our delegates have acted. Our organization has acted. Are we with it?

JOHN F. CONLY, M.D.

BOOK RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Diagnosis in Gynecology. A classification of gynecological diseases based on aetiology and the clinical logic for diagnosis. By James V. Ricci, M.D., clinical professor of gynecology and obstetrics, New York Medical College, director of gynecology of the City Hospital, New York, director of gynecology and obstetrics, Columbus Hospital, attending gynecologist and obstetrician, Flower and Fifth Avenue Hospitals, New York, and consultant in gynecology and obstetrics, Beekman-Downtown Hospital, New York. 8°, cloth, 259 pp. Philadelphia: The Blakiston Company, 1948. \$4.50.

This manual is based on the clinical demonstrations given to students of the New York Medical College. A fundamental knowledge of gynecology is necessary for its profitable use. A new type of classification by genital structures and their diseases is used instead of the usual classification by diseases. The preliminary chapters are devoted to the general subjects of anatomy, female sex hormones, diagnosis and symptomatology and general classification. A good index concludes the volume. The book is well published.

NOTICES

ANNOUNCEMENT

Dr. Joseph A. Dubins announces the removal of his office to 314 Commonwealth Avenue, Physicians Hall, Boston.

NORFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Norfolk District Medical Society will be held at the Boston Medical Library, 8 Fenway, Boston, on Tuesday, January 25, at 8 p.m. The following scientific program, entitled "Geriatrics," will be presented:

Problems of the Aging Theodore G. Klumpp, M.D.

The Surgical Care of the Aged John Homans, M.D.

Medical Aspects of Growing Old Robert T. Monroe, M.D.

The meeting, which will be followed by a collation, is open to all physicians.

NORFOLK DISTRICT WOMEN'S AUXILIARY

A meeting of the Women's Auxiliary of the Norfolk District Medical Society will be held in the State Suite, Copley Plaza Hotel, Boston, on Tuesday, January 25, at 3 p.m. Miss Elizabeth Wilson, actuary, statistician and author, will speak on the subject "Socialized Medicine in England."

INVOLVEMENT OF THE ILEUM IN CHRONIC ULCERATIVE COLITIS*

FRED J. MCCREADY, M.D.,† J. ARNOLD BARGEN, M.D.,‡ MALCOLM B. DOCKERTY, M.D.,§ AND
JOHN M. WAUGH, M.D.¶

ROCHESTER, MINNESOTA

THE fact that extension of the inflammatory process to the terminal portion of the ileum occurs in patients with chronic ulcerative colitis is fairly well known, but it has not received sufficient emphasis. The ileocecal valve does not limit the progress of the lesions of ulcerative colitis into the terminal part of the ileum any more than it prevents secondary involvement of the colon from the ileum in cases of regional enteritis. The type of chronic ulcerative colitis that begins in the rectum and spreads orad may in many cases extend into the terminal part of the ileum, it may continue for great distances up the ileum, and in a few cases it may involve even the jejunum.

It is a well recognized and established fact that so-called regional or segmental or right-sided colitis is associated with a high incidence of ileal involvement. Crohn, Garlock and Yarnis¹ reported the incidence of involvement of the ileum in these cases to be as high as 8 per cent. Borgen and Weber² likewise cited a high incidence of ileal involvement in these cases — namely, 63 per cent. It must be kept in mind that this type of colitis comprises only a very small percentage of all cases of chronic ulcerative colitis. In this paper we are not concerned with the segmental type of colitis, furthermore, we have excluded from this study specific types of inflammation of the ileocecal coil such as those caused by tuberculosis, amebiasis and actinomycosis. We have therefore included only cases of diffuse chronic ulcerative colitis of the thrombo-ulcerative variety — the streptococcal type described by Borgen and Weber² — that characteristically begin in the rectal segment and spread cephalad and, in time, involve the whole colon. It is this variety that makes up the vast majority

of the cases of ulcerative colitis encountered clinically.

To restrict this study to ileums that had been diseased secondary to the type of chronic ulcerative colitis defined above, only cases in which the lesions showed the typical and characteristic proctoscopic and roentgenologic features of this form of colitis were selected. In all the cases the first signs of inflammation were related to the rectum and distal segments of the large bowel as determined on the basis of proctoscopic findings. The shortening and deformity of the entire colon consistent with this type of colitis was noted roentgenologically in all the cases in which studies were made with the aid of barium enemas. These cases were analyzed to determine the incidence, extent, pathological nature, clinical significance and prognosis of ileal involvement in cases of chronic ulcerative colitis.

MATERIAL AND METHODS

This paper comprises a complete pathological study of 23 post-mortem specimens of bowel in cases of diffuse chronic ulcerative colitis in which the ileum was involved and of 6 surgical specimens that included a small segment of the involved terminal part of the ileum, which had been resected along with part or all of the diseased colon. The cases were encountered at the Mayo Clinic from 1935 through 1946.

The clinical records were carefully reviewed to ensure that the cases studied fell into the category already referred to. For this, reliance was placed on the proctoscopic and roentgenologic data. All cases not conforming to these criteria were purposely omitted.

All the gross specimens, surgical and post mortem, utilized in this study had been preserved in 10 per cent formalin at the Mayo Clinic Museum. Each gross specimen was inspected to determine the nature and extent of the gross involvement of the ileum. Multiple blocks of tissue were removed from various areas of ileal involvement. These blocks were placed in a fresh 10 per cent solu-

tion of formalin, sectioned on a freezing microtome, stained with hematoxylin and eosin and mounted permanently on glass slides. The slides were studied carefully for the type and extent of ulceration and inflammatory invasion in each of the coats of the ileum.

Since the clinical entity of regional enteritis was not described until 1932 by Crohn, Ginzburg and Oppenheimer³ and since ileal involvement was not to be confused with regional enteritis, no cases encountered before 1935 were included in this study.

HISTORICAL REVIEW

Chronic ulcerative colitis probably was first described in 1875 by Wilks and Moxon⁴ in their lectures on pathologic anatomy. This report makes no mention of whether there was simultaneous involvement of the small intestine. The first record of the recognition of this disease as a pathologic entity was made when Allchin,⁵ in 1885, exhibited before the London Pathological Society a post-mortem specimen illustrating the features of chronic ulcerative colitis. Allchin mentioned the small intestine only to state that it was perfectly normal. In 1888 White⁶ reported a series of cases from Guy's Hospital in London. He presented a detailed description of the lesions encountered in 11 cases of chronic ulcerative colitis of unknown etiology, and it was noteworthy that he showed in 5 of these cases a similar involvement of the ileum of varying degrees. Evidently, since his first case report in 1885, Allchin had encountered cases of chronic ulcerative colitis with some ileal involvement, because writing again in 1909 he⁷ stated that this disease involved the entire bowel from cecum to anus, occasionally even extending into the ileum. In 1915, Hewitt and Howard,⁸ in noting the relation of polyps of the colon to the inflammatory process, described at length the autopsy findings in 2 cases of chronic ulcerative colitis and polyposis. In 1 of these cases definite ulcerative disease in the lower two thirds of the ileum as well as in the colon was described. In 1919 Logan,⁹ of this clinic, presented a statistical study of 117 cases of chronic ulcerative colitis. In 3 of the 13 cases in this group in which autopsy was performed, fresh ulcers in the lower portion of the ileum were noted. Smith,¹⁰ in 1925, presented an excellent, though brief, pathological description of this disease and stated that the ileum was practically never involved in the nonspecific inflammatory process that affected the colon. He offered as a reason for the relative infrequency of involvement of the terminal portion of the ileum the acid reaction in this part of the ileum, which he believed probably protected it from ulceration. From 1926 to 1932 many authors writing about the pathology of chronic ulcerative colitis did not mention ileal involvement. In 1932 Rankin, Barger and Buie¹¹ said that only late in its course, after repeated severe exacerbations, did the disease occa-

sionally pass the ileocecal valve to involve the terminal portion of the ileum. They added that the process in the ileum was less severe or advanced than that in the colon.

Incidence

McKittrick and Miller,¹² in 1935, placed the incidence of ileal involvement in chronic ulcerative colitis at 1.3 per cent in their cases. In 1941 Cave¹³ reported that in 8 out of 81 cases (10 per cent) of chronic ulcerative colitis there was involvement of the ileum. McMillan,¹⁴ writing in 1942, declared that nearly 25 per cent of the cases of diffuse ulcerative colitis were associated with "backwash" into the terminal portion of the ileum. He also commented on the rarity of hyperplastic and granulomatous types of inflammatory reactions in the ileum. In 1944, in describing his technic for ileostomy, Cattell¹⁵ observed that he had found involvement of the ileum in approximately a sixth of his operative cases; he cautioned against making a stoma in an ileum that was involved in an inflammatory process. In the same year Crandon, Kinner and Walker¹⁶ reviewed reports of 16,500 consecutive autopsies to determine the frequency of ileal involvement. They found 44 cases in which chronic ulcerative colitis was considered the cause of death. In 17 of these cases, or 39 per cent, there was simultaneous involvement of the small intestine. Dennis,¹⁷ in 1945, probably found the highest incidence (33 per cent) of ileal involvement in this disease from his observations at the time of operation. Before proceeding to do an ileostomy, he routinely resected a small segment of intestine for immediate gross pathological study to rule out ulcerative ileitis at this level. He found the presence of diseased bowel at the site of ileostomy to predispose to the development of postoperative diarrhea and a fecal fistula. Thus, the incidence of ileal involvement reported in the literature varied from 1.3 to 39 per cent.

Pathology

Except for the occasional mention of ileal lesions in chronic ulcerative colitis, the medical literature reveals a complete lack of pathological data on this subject. As far as could be ascertained, a few authors have described the gross appearance of involved intestine, but no one had made a combined and detailed gross and microscopical study of the intestine in these cases.

Most authors, including Baird,¹⁸ Barger,¹⁹ Cave,¹³ Colp,²¹ Crohn and Rosenak²² and McMillan,¹⁴ who have observed ileal involvement in chronic ulcerative colitis apparently believed that it merely represented a retrograde extension of the inflammatory process through the ileocecal valve, a sort of "backwash" into the terminal portion of the ileum. Crohn and Rosenak,²² in describing the gross pathological appearance of the ileum in chronic

ulcerative colitis, contended that the disease in the ileum is a destructive and denuding process as it is in the colon. They differentiated the process grossly from that seen in primary ileitis in that the ileum failed to present the hyperplastic, stenotic and granulomatous appearance that is characteristic of primary ileitis but showed only the flat superficial ulcerations characteristic of the colon in chronic ulcerative colitis. To show how chronic ulcerative colitis can involve the ileum they described a striking example in which the ulcerations caused by colitis involved the ileum in a previously made ileosigmoidal stoma, with subsequent perforations of the ileum and generalized peritonitis. Mallory²³ described a case, encountered at autopsy, of chronic ulcerative colitis with ileal involvement and brought up the question of the pathologist's ability to differentiate on anatomic and histologic grounds, the ileum in chronic ulcerative colitis from the ileum in regional ileitis. He expressed the belief that these two different clinical entities can be definitely distinguished from each other on the basis of the pathological appearance of the ileum.

Mallory²⁴ described the histologic picture of regional ileitis, referring to the characteristic and typical pseudotubercle formation, the marked inflammatory invasion of the deeper layers of the bowel wall and the tendency to fistula formation, in contrast, he commented on the absence of these features in the ileum involved as a result of extension of chronic ulcerative colitis. Ulceration and denudation seemed to these authors to be the prominent gross pathological features in the ileum involved as a result of extension of chronic ulcerative colitis.

Although Cave²⁰ recognized the probability that ileal involvement in chronic ulcerative colitis occurs as a result of a continuation or spread of the process backward through the ileocecal valve, he mentioned the fact that in 7 of the 80 patients on whom he operated primarily for ulcerative colitis, he found inflammatory lesions in the small intestine resembling those of regional enteritis.

Few writers have discussed the complications of ileal involvement in chronic ulcerative colitis. Castleman²⁵ reported a case of chronic ulcerative colitis in which perforation of the ileum occurred. The ileum was remarkably hemorrhagic and thin, and when it was opened there were numerous ulcers measuring 1 to 2 cm in diameter, 3 of which had perforated. These ulcerations had appeared proximal to a previously made ileal stoma. Crandon, Kinney and Walker¹⁶ reported 2 cases of ileal perforations proximal to ileal stomas in chronic ulcerative colitis, the lesions in these ileums were identical with those found in the colon in chronic ulcerative colitis. They presented supportive evidence that the process had existed, at the time of operation, in the ileum above the site elected for enterostomy. These authors also reported a remarkably high

incidence of perforation of the small bowel in their cases. Perforation occurred in lesions of the ileum in 4 of the 17 cases in which there was involvement, an incidence of 24 per cent. This was even higher than the incidence of perforation in the colon itself, which was 16 per cent.

Jankelson, McClure and Sweetsir,²⁶ in 1945, reported 11 cases of acute perforation of the bowel in chronic ulcerative colitis, the mortality rate from the complication being 100 per cent. In 4 of these 11 cases, or 36 per cent, the perforation was in the lower part of the ileum. In the remaining 7 cases some segment of the colon was involved. Corbett,²⁷ writing at the same time, in discussing the complications of ileostomy stated that abscesses and fistulas into adjacent structures and the abdominal wall often formed proximal to the stoma as a result of perforating lesions in the diseased ileum in chronic ulcerative colitis. He reported 2 cases, in 1 of which death occurred as a result of this complication.

MAYO CLINIC SERIES

Incidence of Ileal Involvement

In the selection of the 29 cases that are the subject of this study, the data on 103 cases of diffuse thrombolytic ulcerative colitis were reviewed. All these cases satisfied the proctoscopic and roentgenologic criteria for this study, as outlined above. The data in 81 of these 103 cases were based on post-mortem observation, in 23 of the 81 cases, or 28 per cent, there was definite evidence of ileal involvement. The data in 22 of the 103 cases were based on surgical findings, 6 of the surgically resected colons in these 22 cases showed involvement of the attached ileal segment, an incidence of 27 per cent. The incidence of ileal involvement in the 103 cases of chronic ulcerative colitis was 28 per cent.

Incidence by Age and Sex

Of the 29 patients, 15, or 52 per cent, were males. Twenty-four, or 83 per cent, of the patients were in the first three decades of life, and 5, or 17 per cent, were in the fourth decade. The youngest subject was thirteen years old, and the oldest was forty-seven.

Nature of Disease in Ileum

Gross findings An analysis of the pathological features of the 29 specimens that formed the basis for this study showed that the ileum was affected by one of two inflammatory processes. In 22 cases the terminal portion of the ileum presented a gross pathological picture similar to that found in the corresponding colon — that is, the ileal segment was completely and diffusely involved in ulcerative changes (Fig 1, 2 and 3). In the other 7 cases separate ulcers appeared intermittently in the ileum, the intervening portions of small intestine remaining essentially normal (Fig 4). In all 29 cases the in-

tion of formalin, sectioned on a freezing microtome, stained with hematoxylin and eosin and mounted permanently on glass slides. The slides were studied carefully for the type and extent of ulceration and inflammatory invasion in each of the coats of the ileum.

Since the clinical entity of regional enteritis was not described until 1932 by Crohn, Ginzburg and Oppenheimer³ and since ileal involvement was not to be confused with regional enteritis, no cases encountered before 1935 were included in this study.

HISTORICAL REVIEW

Chronic ulcerative colitis probably was first described in 1875 by Wilks and Moxon⁴ in their lectures on pathologic anatomy. This report makes no mention of whether there was simultaneous involvement of the small intestine. The first record of the recognition of this disease as a pathologic entity was made when Allchin,⁵ in 1885, exhibited before the London Pathological Society a post-mortem specimen illustrating the features of chronic ulcerative colitis. Allchin mentioned the small intestine only to state that it was perfectly normal. In 1888 White⁶ reported a series of cases from Guy's Hospital in London. He presented a detailed description of the lesions encountered in 11 cases of chronic ulcerative colitis of unknown etiology, and it was noteworthy that he showed in 5 of these cases a similar involvement of the ileum of varying degrees. Evidently, since his first case report in 1885, Allchin had encountered cases of chronic ulcerative colitis with some ileal involvement, because writing again in 1909 he⁷ stated that this disease involved the entire bowel from cecum to anus, occasionally even extending into the ileum. In 1915, Hewitt and Howard,⁸ in noting the relation of polyps of the colon to the inflammatory process, described at length the autopsy findings in 2 cases of chronic ulcerative colitis and polyposis. In 1 of these cases definite ulcerative disease in the lower two thirds of the ileum as well as in the colon was described. In 1919 Logan,⁹ of this clinic, presented a statistical study of 117 cases of chronic ulcerative colitis. In 3 of the 13 cases in this group in which autopsy was performed, fresh ulcers in the lower portion of the ileum were noted. Smith,¹⁰ in 1925, presented an excellent, though brief, pathological description of this disease and stated that the ileum was practically never involved in the nonspecific inflammatory process that affected the colon. He offered as a reason for the relative infrequency of involvement of the terminal portion of the ileum the acid reaction in this part of the ileum, which he believed probably protected it from ulceration. From 1926 to 1932 many authors writing about the pathology of chronic ulcerative colitis did not mention ileal involvement. In 1932 Rankin, Barger and Buie¹¹ said that only late in its course, after repeated severe exacerbations, did the disease occa-

sionally pass the ileocecal valve to involve the terminal portion of the ileum. They added that the process in the ileum was less severe or advanced than that in the colon.

Incidence

McKittrick and Miller,¹² in 1935, placed the incidence of ileal involvement in chronic ulcerative colitis at 1.3 per cent in their cases. In 1941 Cave¹³ reported that in 8 out of 81 cases (10 per cent) of chronic ulcerative colitis there was involvement of the ileum. McMillan,¹⁴ writing in 1942, declared that nearly 25 per cent of the cases of diffuse ulcerative colitis were associated with "backwash" into the terminal portion of the ileum. He also commented on the rarity of hyperplastic and granulomatous types of inflammatory reactions in the ileum. In 1944, in describing his technic for ileostomy, Cattell¹⁵ observed that he had found involvement of the ileum in approximately a sixth of his operative cases, he cautioned against making a stoma in an ileum that was involved in an inflammatory process. In the same year Crandon, Kinney and Walker¹⁶ reviewed reports of 16,500 consecutive autopsies to determine the frequency of ileal involvement. They found 44 cases in which chronic ulcerative colitis was considered the cause of death. In 17 of these cases, or 39 per cent, there was simultaneous involvement of the small intestine. Dennis,¹⁷ in 1945, probably found the highest incidence (33 per cent) of ileal involvement in this disease from his observations at the time of operation. Before proceeding to do an ileostomy, he routinely resected a small segment of intestine for immediate gross pathological study to rule out ulcerative ileitis at this level. He found the presence of diseased bowel at the site of ileostomy to predispose to the development of postoperative diarrhea and a fecal fistula. Thus, the incidence of ileal involvement reported in the literature varied from 1.3 to 39 per cent.

Pathology

Except for the occasional mention of ileal lesions in chronic ulcerative colitis, the medical literature reveals a complete lack of pathological data on this subject. As far as could be ascertained, a few authors have described the gross appearance of involved intestine, but no one had made a combined and detailed gross and microscopical study of the intestine in these cases.

Most authors, including Baird,¹⁸ Barger,¹⁹ Cave,²⁰ Colp,²¹ Crohn and Rosenak²² and McMillan,¹⁴ who have observed ileal involvement in chronic ulcerative colitis apparently believed that it merely represented a retrograde extension of the inflammatory process through the ileocecal valve, a sort of "backwash" into the terminal portion of the ileum. Crohn and Rosenak,²² in describing the gross pathological appearance of the ileum in chronic

or oval ones were occasionally seen. The long axes of the solitary lesions were either longitudinal or transverse in relation to the ileum. The bases of the ulcers were for the most part fibrotic and granular in appearance. The edges were sharp and well defined. Occasionally, the surrounding mucosa was reddened or congested, but more often the near-by tissues were completely free of evidence of any gross inflammatory reaction. The ulcerations did not have any constant relation to the mesentery as seen in regional enteritis but were distributed over the whole lumen of the small intestine.

None of the 29 specimens showed either diffuse or localized thickening of the wall of the ileum, even though in a few cases the corresponding wall of the colon was excessively thickened, with marked stricture of the intestinal lumen. Although it was quite obvious even to the naked eye that there was

FIGURE 5 Section of the Entire Wall of the Ileum in a Case of Diffuse Thrombo-ulcerative Colitis

Note the mucosal ulcerations. The submucosa, muscularis and serosa are essentially normal. The wall is not thickened (hematoxylin and eosin stain — $\times 81\frac{1}{2}$)

no great thickening of the involved ileal walls, a measurement of the thickness was made in all cases, it was found that in none was the wall more than 3 or 4 mm thick. In 26 cases the thickness was within the normal limits of 2 or 3 mm. None of the walls resembled the thick boggy ileal walls seen in specimens representative of regional enteritis. As we expected in the absence of thickening of the ileal walls, none of the 29 ileums revealed any stenosis of the intestinal lumen such as that frequently seen in regional enteritis.

Extent of involvement. The ulcerations may involve only the last few centimeters of the ileum, or they may be scattered over a distance of a few feet. Occasionally, they are found simultaneously in the upper part of the ileum and jejunum. It was possible to determine the exact extent of ileal involvement only in the post-mortem specimens (23 in number) because in only these cases was all of the small bowel available for examination. In the 17 cases in which there was diffuse involvement of the terminal part of the ileum, the average length of ileum affected was 20 cm, the shortest being 4 cm and the longest 45 cm.

Of the 7 specimens presenting patchy intermittent ulcerations, 3 showed ulcers that extended intermittently over several feet of the lower and upper portions of the ileum, and the other 4 revealed simultaneous involvement of both the ileum and the jejunum with multiple, well defined ulcers. It is of some interest that of the 23 post-mortem specimens, at least 30 cm of the terminal part of the ileum was involved in 6 and 45 cm in 3.

In the 6 surgical specimens in which part of the ileum was resected along with the right portion of the colon, only a small segment was available for study, the longest being 50 cm and the average 20 cm. In only 3 of these surgical specimens was there enough obviously normal ileum proximal to the diseased segment to permit determination of the exact length of the part involved, in these cases 12 cm of the ileum, on the average, was affected. In the other 3 the inflammatory change was present over the whole segment of the terminal portion of the ileum and ran right up to the point of resection. The length of the ileal segment involved was 4, 5 and 30 cm, respectively, but for reasons stated above, if more of the ileum had been available, perhaps the length of diseased ileum would have been even greater.

Microscopical findings. As was seen from a review of the gross specimens, ulceration and denudation were the predominant features in the mucosal coat (Fig. 5). Ulceration of some degree was present in the ileum of all 29 specimens, in some it was superficial and consisted mostly of erosions and atrophy of the epithelium, but in others it was deep, with a good deal of sloughing and necrosis. An attempt was made to place the ulcers of the ileum, on the basis of microscopical appearance, in the following three groups according to their depth of penetration: ulceration to and including the muscularis mucosae (20 specimens), ulceration through the submucosa (4 specimens), and ulceration through the main muscular layers and serosa with perforation (5 specimens). It was noted that the depth of the ulcers was independent of their gross distribution and character. Many of the solitary ulcers penetrated through all the coats of the bowel, whereas many of the diffuse ulcerations were superficial in character and were associated with little inflammatory invasion of the other coats.

Histologically, in the base of the ulcers the usual three typical zones were seen: zone of necrosis, zone of inflammatory reaction characterized by edema, vascular engorgement and infiltration with polymorphonuclear leukocytes, lymphocytes and plasma cells, and zone characterized by the presence of various amounts of granulation tissue and collagenous connective tissue.

Some authors classify ulcers as acute or chronic. Twenty-four of the specimens showed ulcerations that were chronic, with a predominance of lymphocytes and plasma cells and only a mild degree of

flammatory reaction was much milder and far less advanced than that seen in the diseased colon. This is in agreement with previous observations made by Rankin, Barger and Buie.¹¹

The severer degree of inflammatory changes in the ileum was found in the 22 cases in which the

lines of longitudinally running ulcerations. The ulcers were irregular and exhibited a great deal of undermining and coalescing. The gross features

terminal part of the ileum presented to the naked eye the same gross appearance as that found in the chronically diseased colon. The ulceration of the mucosa of the ileum in these cases was so marked

in these cases resembled greatly those of polyposis cystica of Virchow, which also is characteristically manifest in the colon in the same cases.

In the other 7 cases the disease was not quite so denuding or destructive, although ulcerative changes in the ileum occurred. These specimens did not reveal the involvement as a diffuse process continuing back from the colon but showed multiple ulcers that had a scattered or patchy distribution, leaving variable amounts of relatively nor-

FIGURE 2 *Diffuse Thrombolytic Colitis in the Colon, with Some Extension into the Terminal Part of the Ileum. The terminal segment is diffusely ulcerated*

that there was almost complete loss of the mucosa except for a few polypoid islands of mucosa. There was complete loss of the transverse folds and villi of the ileum. The inflammatory process represented a direct continuation of the changes in the colon through the ileocecal valve, characterized by long

mal mucosa between them. These ulcers, which varied from 2 cm to 2 or 3 mm in diameter, were for the most part irregular in shape, although round

or oval ones were occasionally seen. The long axes of the solitary lesions were either longitudinal or transverse in relation to the ileum. The bases of the ulcers were for the most part fibrotic and granular in appearance. The edges were sharp and well defined. Occasionally, the surrounding mucosa was reddened or congested, but more often the near-by tissues were completely free of evidence of any gross inflammatory reaction. The ulcerations did not have any constant relation to the mesentery as seen in regional enteritis but were distributed over the whole lumen of the small intestine.

None of the 29 specimens showed either diffuse or localized thickening of the wall of the ileum, even though in a few cases the corresponding wall of the colon was excessively thickened, with marked stricture of the intestinal lumen. Although it was quite obvious even to the naked eye that there was

FIGURE 5 Section of the Entire Wall of the Ileum in a Case of Diffuse Thromboalcerative Colitis

no great thickening of the involved ileal walls, a measurement of the thickness was made in all cases, it was found that in none was the wall more than 3 or 4 mm thick. In 26 cases the thickness was within the normal limits of 2 or 3 mm. None of the walls resembled the thick boggy ileal walls seen in specimens representative of regional enteritis. As we expected in the absence of thickening of the ileal walls, none of the 29 ileums revealed any stenosis of the intestinal lumen such as that frequently seen in regional enteritis.

Extent of involvement. The ulcerations may involve only the last few centimeters of the ileum, or they may be scattered over a distance of a few feet. Occasionally, they are found simultaneously in the upper part of the ileum and jejunum. It was possible to determine the exact extent of ileal involvement only in the post-mortem specimens (23 in number) because in only these cases was all of the small bowel available for examination. In the 17 cases in which there was diffuse involvement of the terminal part of the ileum, the average length of ileum affected was 20 cm, the shortest being 4 cm and the longest 45 cm.

Of the 7 specimens presenting patchy intermittent ulcerations, 3 showed ulcers that extended intermittently over several feet of the lower and upper portions of the ileum, and the other 4 revealed simultaneous involvement of both the ileum and the jejunum with multiple, well defined ulcers. It is of some interest that of the 23 post-mortem specimens, at least 30 cm of the terminal part of the ileum was involved in 6 and 45 cm in 3.

In the 6 surgical specimens in which part of the ileum was resected along with the right portion of the colon, only a small segment was available for study, the longest being 50 cm and the average 20 cm. In only 3 of these surgical specimens was there enough obviously normal ileum proximal to the diseased segment to permit determination of the exact length of the part involved, in these cases 12 cm of the ileum, on the average, was affected. In the other 3 the inflammatory change was present over the whole segment of the terminal portion of the ileum and ran right up to the point of resection. The length of the ileal segment involved was 4, 5 and 30 cm, respectively, but for reasons stated above, if more of the ileum had been available, perhaps the length of diseased ileum would have been even greater.

Microscopical findings. As was seen from a review of the gross specimens, ulceration and denudation were the predominant features in the mucosal coat (Fig 5). Ulceration of some degree was present in the ileum of all 29 specimens, in some it was superficial and consisted mostly of erosions and atrophy of the epithelium, but in others it was deep, with a good deal of sloughing and necrosis. An attempt was made to place the ulcers of the ileum, on the basis of microscopical appearance, in the following three groups according to their depth of penetration: ulceration to and including the muscularis mucosae (20 specimens), ulceration through the submucosa (4 specimens), and ulceration through the main muscular layers and serosa with perforation (5 specimens). It was noted that the depth of the ulcers was independent of their gross distribution and character. Many of the solitary ulcers penetrated through all the coats of the bowel, whereas many of the diffuse ulcerations were superficial in character and were associated with little inflammatory invasion of the other coats.

Histologically, in the base of the ulcers the usual three typical zones were seen: zone of necrosis, zone of inflammatory reaction characterized by edema, vascular engorgement and infiltration with polymorphonuclear leukocytes, lymphocytes and plasma cells, and zone characterized by the presence of various amounts of granulation tissue and collagenous connective tissue.

Some authors classify ulcers as acute or chronic. Twenty-four of the specimens showed ulcerations that were chronic, with a predominance of lymphocytes and plasma cells and only a mild degree of

acute polymorphonuclear leukocytic reaction. The 5 specimens that revealed marked degrees of acute inflammatory change were those in which ileal ulcers had resulted in perforation.

In 15 of the 29 cases there was a mild to moderate proliferative thickening of the muscular elements of the muscularis mucosae but not to the marked degree that is seen in cases of regional enteritis. Throughout the submucosa there was a minimal degree of edema, chronic nonspecific granulation tissue and cellular infiltration with aggregations of lymphocytes, mononuclear cells and plasma cells.

FIGURE 6 Diffuse Thrombolytic Colitis of the Entire Colon, with Involvement of More than 30 cm of the Terminal Part of the Ileum

Only the 5 specimens with more acute ulcerations displayed any great degree of polymorphonuclear leukocytic infiltration, and this was found at the base of the ulcers. There was moderate dilatation of the lymphatic channels and congestion of the blood capillaries. Hemorrhage and thrombosis, features described by Bargen¹⁹ as characteristically appearing in the colon, were present in most of the sections but not to the same pronounced degree as seen in the colon. The most characteristic feature was the comparatively minor edematous fibroblastic reaction and fibroplasia, which was minimal when compared with that which is found in the submucosa in cases of regional enteritis.

There was no obvious hypertrophy of the internal and external coats of the muscularis propria in any of the 29 cases. Except in the 5 cases in which there was penetration of the ulcer to the serosal layer and general peritonitis along with the usual degree of thickening with inflammatory exudate, the serosa

was normal in all respects in the 29 cases. Small focal collections of epithelioid cells, lymphocytes and giant cells without caseation, referred to as pseudotubercles, were not seen in any of 29 cases of chronic ulcerative colitis, whereas in 30 per cent of the cases of regional enteritis this is a fairly frequent finding. Hadfield,²⁸ Owens²⁹ and Shapiro³⁰ have made reference to this finding in regional enteritis. A study of lymph nodes and mesentery was by necessity omitted from this investigation inasmuch as they were not available for the majority of specimens studied.

Röntgenologic findings. Of the 29 cases, in 10 there were no studies made with the aid of barium enemas, owing to the critical condition of the patient. In 4 of the remaining 19 cases the roentgenologic report mentioned involvement of the terminal part of the ileum by the pathologic

FIGURE 7 Diffuse Thrombolytic Colitis of the Entire Colon, with Extension into the Ileum for a Distance of Approximately 60 cm

process. A recent survey of the roentgenograms revealed definite evidence of ileal disease in another 6 cases, thus making a total of 10 cases of 19 (more than 50 per cent) in which ileal involvement was demonstrated by means of barium-enema studies. The average length of the segment involved as noted in the roentgenologic studies was approximately 1 foot (30 cm) of the terminal part of the ileum proximal to the ileocecal junction. This involve-

ment was continuous with that of the diseased colon. Eight of the 10 specimens showed at least 30 cm of involvement, and 2 showed involvement for only a few centimeters according to the roentgenograms. Frequently, the colon in chronic ulcerative colitis is so badly diseased that the roentgenologist does not report the ileal involvement even though roentgenologic evidence is present. Again, the competency or incompetency of the ileocecal valve during the time that barium-enema studies are being made probably plays an important part in determining roentgenologically the point to which the disease has extended into the terminal part of the ileum. Thus, a fair estimate of the true incidence of involvement cannot be obtained on the basis of roentgenologic studies alone (Fig 6 and 7).

Complications Clinical symptoms of mechanical obstruction of the small bowel due to stenosis of the lumen were not observed in any of the 29 cases of chronic ulcerative colitis in which the ileum was involved by ulcerative disease. This was to be expected on the basis of the study of the gross specimens, inasmuch as not a single specimen presented stenosis of the lumen of the small bowel or excessive thickening of the wall, which was found routinely in the cases of chronic regional enteritis.

It was impossible to estimate how often the ulcerations of the involved ileum gave rise to severe hemorrhage or loss of fluid because the process in the colon alone was enough to account for these occurrences. However, excessive loss of fluid from the ileum following an ileostomy has been shown by Crandon, Kinney and Walker¹⁶ to arise from these ulcerations. None of the 8 patients in this series who underwent ileostomy continued to bleed from the ileal stoma or to lose an excessive amount of fluid after operation, but it must be remembered that all these patients succumbed very shortly after operation. Only 1 of the 8 patients survived longer than three weeks, and he died within two months of the date of ileostomy.

Perforation of the ileal ulcers is without doubt the most dangerous of all the complications of ileal involvement in chronic ulcerative colitis because it apparently invariably results in generalized peritonitis and death. As mentioned above, in 5 of the 29 cases (17 per cent) this complication occurred. One patient presented six solitary ulcers, one of which had perforated after ileostomy. This patient died three weeks later of generalized peritonitis and multiple ulcers were demonstrated in the ileum proximal to the ileal stoma. Crandon, Kinney and Walker¹⁶ reported a 24 per cent incidence of perforative lesions of the small bowel in cases of ulcerative ileitis.

Clinical significance In attempting to evaluate the clinical significance of involvement of the ileum in chronic ulcerative colitis it should be demonstrated whether this involvement occurs relatively

early in the course of the disease or whether it is, for the most part, a very late complication — a sort of terminal event in the downhill progress of the disease. Therefore, it is important to know when the ulcers make their appearance in the ileum. Crandon, Kinney and Walker¹⁶ have shown that ileal involvement may appear early in the course of the disease. In an analysis of our 29 cases the only way that we could determine whether the ileum was involved relatively early or whether the involvement occurred merely as a terminal event in the course of the disease was by means of a study of the cases in which there was roentgenologic evidence of ileal involvement or by means of a study of the surgical cases. In 3 cases disease of the ileum was demonstrated roentgenologically one month, two months and three years respectively before death. In the 6 surgical cases, from one to seven years elapsed from the time that involvement was described at operation to the time of the present study. Certainly, in none of these cases could the involvement be called a terminal event of an intractable colitis, therefore, its occurrence must have been of more than academic interest.

A further analysis was made to determine whether the severity or course of colonic disease had any relation to the involvement of the ileum. We were interested in seeing whether the patients who had acute fulminating ulcerative colitis that might terminate fatally in a very short time were more prone to have ileal involvement than those with disease that was characterized by a long, chronic course of remissions and exacerbations. In 8 of the 23 cases in which autopsy was performed there had been a rather acute fulminating course of a year or less from the onset of symptoms to death, in the other 15 cases the course was chronic. Therefore, it is apparent that ileal involvement occurs both in cases of acute fulminating disease and in those of long-standing chronic disease. It is also of clinical significance that in only 1 of the 8 cases of acute disease were the ulcerations so severe that they resulted in perforation of the ileum. In the other 4 cases of perforation the disease was definitely chronic.

What, then, is the importance of ileal involvement in chronic ulcerative colitis? How may the prognosis be affected by this involvement? When an operation such as ileostomy is performed in this disease and the terminal part of the ileum is simultaneously involved in the inflammatory process, a high mortality and a poor operative result may be obtained.

Ileostomy in chronic ulcerative colitis is accompanied by a very high mortality. In 1932 Bargen, Brown and Rankin²¹ reported a mortality of 66 per cent for emergency and 50 per cent for elective ileostomy. In 1935 McKittrick and Miller¹² observed a mortality of 35 per cent. Cave and Thompson,²² in 1941, reported an over-all mortality

acute polymorphonuclear leukocytic reaction. The 5 specimens that revealed marked degrees of acute inflammatory change were those in which ileal ulcers had resulted in perforation.

In 15 of the 29 cases there was a mild to moderate proliferative thickening of the muscular elements of the muscularis mucosae but not to the marked degree that is seen in cases of regional enteritis. Throughout the submucosa there was a minimal degree of edema, chronic nonspecific granulation tissue and cellular infiltration with aggregations of lymphocytes, mononuclear cells and plasma cells.

CANCER OF THE LOWER LARGE BOWEL*

Results in 100 Cases

ISAAC M WEBBER, M D †

PORTLAND MAINE

THE intent of this survey is to present an investigation of facts pertinent to the care of 100 consecutive patients with cancer involving the lower segments of the large bowel and to offer an appraisal of the therapeutic effort employed in their management.

This series includes both service and private patients at the Maine General Hospital, private patients at the Eye and Ear Infirmary and the Mercy Hospital, all of Portland, and one or more patients treated in each of six other institutions in outlying towns. It is obvious, then, that no one of these patients received all the advantages available in the university or large medical center. Furthermore, some of the results obtained reflect earlier and less experienced endeavor before the advent of the sulfonamide or antibiotic remedies and before the value of fluid, electrolytic, vitamin and protein deficiencies was fully appreciated.

From the current literature and from my own observation, the impression is gained that cancer of the large bowel is neither diagnosed nor subjected to operation appreciably earlier than it was ten or more years ago. Yet intestinal cancer, like any malignant lesion, has an early stage when the growth is small, sharply circumscribed and therefore readily extirpated. Just how long cancer in its early phase exists in the bowel without producing symptoms is yet to be determined, unfortunately, the process remains quiescent without manifestation until certain complications signal the presence of danger.

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 1, 1945.

†Chief surgical staff, Maine General Hospital.

It is common knowledge that when a tumor of the bowel becomes sufficiently ulcerated the process may manifest itself by either gross or occult blood in the stool—an occult blood loss at times so insidious that only anemia is evident, the malignant lesion being otherwise asymptomatic. A cancerous mass, having acquired sufficient size and inflammatory reaction, or having compromised the bowel lumen, may produce enough irritation to promote frequent or liquid stools and in some cases dejections composed largely of mucus, either with or without local or abdominal discomfort as an associated symptom. These manifestations are the obvious signs and symptoms that warn both patient and physician of impending danger, but too many practitioners appear to be unmindful of the fact that such complaints indicate not early cancer but the complications of a well established malignant tumor urgently in need of attention.

Inasmuch as complaints referable to the terminal segments of the large intestine ordinarily bespeak the existence of a benign disorder, the average person with such an ailment is apt to assume that he is suffering from one of the more prevalent conditions such as piles, colitis and diarrhea and often employs self-medication for months. That the physician too often acquiesces in this frequently fallacious assumption or initiates the idea himself, instead of insisting that the patient have the benefit of a thorough rectal examination is perhaps only natural since it has been estimated that the average practitioner rarely encounters more than one or two patients with cancer of the rectum and, therefore, is not rendered sufficiently cancer-

of 25 per cent for ileostomy, the rate being 50 per cent for emergency operations and 9 per cent for elective operations. In the same year Lahey³³ reported a mortality of 20 per cent for ileostomy in chronic ulcerative colitis. Many circumstances have been held responsible for the high mortality rate and the high incidence of failure of ileostomy in this disease. We wish to emphasize the fact that involvement of the ileum by ulcerative disease is one of the commonest and yet infrequently mentioned factors in the high mortality rate and the frequent failure of ileostomy in chronic ulcerative colitis.

Of course, it is agreed by most surgeons that extensive exploration of the peritoneal cavity and excessive handling of the diseased bowel in the acute stage of chronic ulcerative colitis is contraindicated. Nevertheless, enough exploration and examination of the distal part of the ileum must be done to exclude the diagnosis of inflammatory changes in this segment. Dennis¹⁷ has emphasized this point. He routinely sections a small segment of ileum for gross examination of the mucosa prior to establishing the site for the ileal stoma to avoid placing the stoma in a diseased segment of the small bowel. Involvement of the ileum in chronic ulcerative colitis is probably a definite contraindication to the performance of ileostomy unless the ileal stoma can be placed well above any area in which there is gross or microscopical involvement. Eight of the 23 patients who came to autopsy had had a previous ileostomy. The longest period of survival was sixty days, and the shortest five days.

SUMMARY AND CONCLUSIONS

A study is presented of 23 necropsy specimens of the bowel in cases of chronic ulcerative colitis of the diffuse thromboulcerative variety with ileal involvement encountered at the Mayo Clinic from 1935 to 1946. In addition, the ileum in 6 surgically removed specimens of the bowel in cases of chronic ulcerative colitis with ileal involvement was studied. These 29 specimens were selected from 81 autopsy and 22 surgical specimens of the bowel in cases of chronic ulcerative colitis in which the proctoscopic and roentgenologic criteria outlined were met. The incidence of ileal involvement in the 103 cases was 28 per cent. Six of the 22 surgically removed specimens showed ileal involvement, giving an incidence of 27 per cent, 23 of 81 autopsy specimens revealed such involvement, giving an incidence of 28 per cent. The incidence of ileal involvement reported in the literature varied from 13 to 39 per cent.

The average length of the segment of ileum affected in the cases in which the pathologic changes were diffuse was 20 cm., with variations from 4 to 45 cm. In 7 of the 29 cases solitary ulcers were present, sometimes extending throughout the length of the small bowel.

The nature of the disease in the ileum was similar to that found in the colon. It was essentially denuding and ulcerative. Twenty-two cases were diffusely ulcerative, and in 7 the ileum presented multiple solitary ulcers.

Roentgenologic evidence of ileal involvement was found in 10 of 19 cases in which barium-enema studies were carried out.

Perforation of the ulcerations of the ileum, with generalized peritonitis, was a very serious complication that occurred in 5 of the 29 cases, or 17 per cent. In 4 of the 5 cases perforation occurred almost immediately after the performance of ileostomy.

The duration of the disease showed no definite relation to the incidence of ileal involvement. Eight of the 23 patients who came to autopsy (35 per cent) ran an acute fulminating course of one year's duration or less, whereas the remaining 15 patients (65 per cent) had a long chronic course lasting from five to fifteen years.

Ileal involvement in chronic ulcerative colitis is not necessarily a terminal event of an intractable colitis as is assumed by many authors. In 9 of the 29 cases (31 per cent), the ileum was definitely shown, on the basis of surgical or roentgenologic data, to be involved relatively early in the course of the disease.

The ileum is involved in chronic ulcerative colitis more often than is generally realized, and this finding should therefore be looked for in all cases of diffuse chronic ulcerative colitis.

Knowledge of the presence and extent of ileal involvement in chronic ulcerative colitis is an important consideration if surgical treatment is deemed necessary.

Ileostomy for chronic ulcerative colitis performed through a segment of ileum that is the site of ulcerative inflammatory changes will probably produce a poor operative result. Perhaps this is one of the important considerations responsible for the high mortality associated with ileostomy in the treatment of this disease.

Involvement of the ileum is probably one of the factors that retard the healing process in the colon in chronic ulcerative colitis.

CANCER OF THE LOWER LARGE BOWEL*

Results in 100 Cases

ISAAC M. WEBBER, M D †

PORTLAND, MAINE

THE intent of this survey is to present an investigation of facts pertinent to the care of 100 consecutive patients with cancer involving the lower segments of the large bowel and to offer an appraisal of the therapeutic effort employed in their management.

This series includes both service and private patients at the Maine General Hospital, private patients at the Eye and Ear Infirmary and the Mercy Hospital, all of Portland, and one or more patients treated in each of six other institutions in outlying towns. It is obvious, then, that no one of these patients received all the advantages available in the university or large medical center. Furthermore, some of the results obtained reflect earlier and less experienced endeavor before the advent of the sulfonamide or antibiotic remedies and before the value of fluid, electrolytic, vitamin and protein deficiencies was fully appreciated.

From the current literature and from my own observation, the impression is gained that cancer of the large bowel is neither diagnosed nor subjected to operation appreciably earlier than it was ten or more years ago. Yet intestinal cancer, like any malignant lesion, has an early stage when the growth is small, sharply circumscribed and therefore readily extirpated. Just how long cancer in its early phase exists in the bowel without producing symptoms is yet to be determined; unfortunately, the process remains quiescent without manifestation until certain complications signal the presence of danger.

It is common knowledge that when a tumor of the bowel becomes sufficiently ulcerated the process may manifest itself by either gross or occult blood in the stool—an occult blood loss at times so insidious that only anemia is evident, the malignant lesion being otherwise asymptomatic. A cancerous mass, having acquired sufficient size and inflammatory reaction, or having compromised the bowel lumen, may produce enough irritation to promote frequent or liquid stools and in some cases dejections composed largely of mucus, either with or without local or abdominal discomfort as an associated symptom. These manifestations are the obvious signs and symptoms that warn both patient and physician of impending danger, but too many practitioners appear to be unmindful of the fact that such complaints indicate not early cancer but the complications of a well established malignant tumor urgently in need of attention.

Inasmuch as complaints referable to the terminal segments of the large intestine ordinarily bespeak the existence of a benign disorder, the average person with such an ailment is apt to assume that he is suffering from one of the more prevalent conditions such as piles, colitis and diarrhea and often employs self-medication for months. That the physician too often acquiesces in this frequently fallacious assumption or initiates the idea himself, instead of insisting that the patient have the benefit of a thorough rectal examination, is perhaps only natural since it has been estimated that the average practitioner rarely encounters yearly more than one or two patients with cancer of the rectum and, therefore, is not rendered sufficiently cancer-

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 1, 1948.

†Chief surgical staff, Maine General Hospital.

conscious to recognize the fact that a malignant tumor should be the primary consideration to be confirmed or rejected only after appropriate investigation. Physicians do not appear constantly alert to the fact that 70 per cent of all cancer of the large intestine can be either actually palpated or made accessible to the eye by use of the sigmoidoscope, whereas it frequently escapes detection by the conventional barium-enema x-ray study.

Although progress in the field of establishing the presence of cancer in the earlier phases of its development is grievously lacking, ground has unquestionably been gained in the field of therapy. In recent years a greater number of the more extensive and inaccessible malignant tumors of the alimentary tract have been resected with increasing degrees of success. The fact has become well established that morbidity and mortality rates in the management of colonic and rectal cancers have definitely lowered, and, since the healing process of the body is influenced by a variety of factors, few surgeons have been sufficiently speculative to ascribe this more recent decline to any solitary factor.

In 1942, however, in reporting his experience with one-stage abdominoperineal resections, Jones¹ noted that the incidence of abdominal-wound infection was in direct relation to the number of

ment but to the activity of the sulfonamide compound. Furthermore, because of that same agent, the two most lethal complications of large-bowel resection fell precipitously, peritonitis from 6.1 per cent before the sulfonamide era to 1.8 per cent after it and, correspondingly, bronchopneumonia from 2.2 to 0.7 per cent.

Although the years 1940 and 1942, as mentioned respectively by Pemberton² and Jones,¹ may have witnessed a substantial decline in morbidity and mortality owing to the influence of single, solitary factors such as the innocuousness of suture material on the one hand and the bactericidal effect of sulfonamides on the other, it is noteworthy that the year 1942 has been designated by McKittrick³ as

TABLE 2 Hospital Deaths

GROUP	FATAL COMPLICATIONS	NO. OF DEATHS
First 50 patients (40 resections)	Bronchopneumonia	2
	Peritonitis	1
	Volvulus small bowel	1
	Cerebral hemorrhage	1
	Undetermined (no autopsy)	3
Second 50 patients (45 resections)	0	0

peritoneal and pulmonary complications. He expressed the opinion that postoperative peritonitis was always secondary to an infected wound, and he implied that, by removal of the hazard of infection from the incision by the use of steel wire sutures, peritoneal infection had been practically eliminated. Furthermore, during this period of the metallic suture, which was the only change in management, the incidence of hospital deaths dropped from 12 to 4.5 per cent, and he stated, "I am convinced that this type of closure is accountable for most of the success." During the year 1940 the morbidity and mortality in colonic and rectal surgery at the Mayo Clinic, according to Pemberton² also dropped rather abruptly from approximately 15 to 5 per cent. This improvement was credited not to a change in technic or manage-

the period of transition from the earlier to present methods. He has expressed the opinion that as the result of adherence to meticulous technic and essential basic surgical principles, without dependence on chemotherapeutic and antibiotic agents or on staged operations, the death rate of 11 per cent prior to 1942 has fallen to 3.6 per cent. In the present survey it is an interesting coincidence that of the first 50 patients, the 40 who underwent resection prior to the year 1941 suffered a 20 per cent hospital mortality but that of the second 50 patients the 45 who were subjected to similar treatment experienced no mortality.

An appraisal by the surgeon of his own work should be of assistance in modifying methods or practices for the benefit of those patients entrusted to his care. A prerequisite, of course, is that he know what is being accomplished by other workers in the same field of endeavor under similar as well as more favorable conditions and that he be familiar with the natural history of the disease under consideration. The latter information on rectal cancer in this country was made available in 1935 when Daland, Welch and Nathanson⁴ reported the end results in 100 untreated cancers of the rectum. In their record we find that, although a single patient lingered for forty-nine months, the median length of life was only fourteen months from onset of symptoms to death. All patients were miserable while they awaited the inevitable, and all died with cancer. Also during that period from 19 different hospitals, 10 of which were in Boston, these investigators found the prevailing operative mortality

to be 26 per cent and, operative deaths excluded, the five-year survival rate to be 41 per cent. Since these findings were recorded, mortality and longevity figures have continuously improved.

The various types of operative procedure employed in the group of patients here presented are recorded in Table 1. The wisdom exercised in performing 14 segmental resections with end-to-end anastomosis for cancer of the rectosigmoidal region can be properly questioned since such an operation does not remove the greatest possible amount of contiguous and regional lymph-node tissues. But regardless of the fact that Glover and Waugh⁵ justify the less radical operation with preservation of the anal sphincter as a result of their investigation of lymph-node metastasis in cancer of the "recto-sigmoid region," and despite the fact that Gilchrist and David⁶ present evidence against the advisability of such a procedure as a result of an investigation of the same problem, under certain conditions it has seemed to me that the interests of the patient could be best served by the less radical operation. Complete loss of vision, loss of vision with profound deafness, liver metastasis and an error in interpreting by palpation two hepatomas as metastatic growths were factors that influenced

Such a review may yield information that will prevent the repetition of undesirable occurrences and permit the earlier recognition and treatment of others, thereby reducing morbidity and mortality. Inasmuch as it was my custom to manage the impaired bladder function incident to operative trauma by use of the inlay catheter for seven to twelve days after operation, all patients included in this survey must have had some degree of urinary-tract infection, and yet there were apparently no severe or protracted symptoms of cystitis. With two exceptions the patients were able to void with little or no difficulty at the time of dismissal from the hospital. These two irregularities and all other serious, nonfatal complications are recorded in Table 4.

The circumstance that new cancers develop and others reappear years after the initial lesion has been removed presents another aspect of the present-day attitude toward management. The

me to preserve the anal sphincter. A better service to others in this sub-group might have been derived from the more radical Miles resection.

Hospital deaths for all patients who underwent resection are listed in Table 2.

The one feature of surgical treatment of large-bowel cancer on which all surgeons of experience appear to be in accord is that a procedure aimed at relief that fails to remove the primary growth, except possibly in the presence of a high degree of obstruction, gives little or no alleviation. Consequently, operative procedures have become more extensive to accomplish this end. As indicated in Table 3, it has likewise been my practice to remove tissues or organs invaded by contact spread, even in the presence of liver metastasis or advanced age of the patient, the eldest being aged eighty-three years.

A critical check of the complications in any series of major procedures is often sobering, if not instruc-

success of a second resection, as recorded by Dunphy,⁷ Young⁸ and others, serves to stress the importance of a thorough examination of the patient whenever disorders suggesting cancer reappear, since long periods of arrest may follow a radical reoperation, with gratifying results to both patient and physician.

Although it has been impossible to determine in my own group of patients how many actually became victims of a recurrence or of a new cancer, both conditions were known to have occurred. One patient has remained in good health for a period of seven years after the removal of the rectal stump with its recurrent cancer, which was discovered and resected twelve months after an anterior resection and colostomy in another hospital. A second patient lived more than six years after the removal of a new sigmoidal cancer, which appeared approximately four years after the extirpation of a malignant lesion of the rectum. A Miles resection, performed on a third patient, disclosed a rectosigmoidal cancer that neither at the operating table nor on examination by a pathologist revealed lymph-node invasion. Unilateral metastatic cancer became manifest six years and three months later in the inguinal and iliac lymph nodes. The perineal and abdominal-wall tissues were free from any recurrence, urinary-tract signs and symptoms were in

abeyance, and a roentgenogram of the spine revealed nothing abnormal. On opening the abdomen I found no disease of the presacral region, peritoneum, liver or organs or tissues other than those mentioned. Consequently, the inguinal and iliac lymph nodes were resected according to the method of Taylor and Nathanson.⁹ The nodes were firm and not adherent to important structures. The largest node measured 3.2 cm in diameter. Two years and three months later, re-examination revealed that the patient was doing manual labor at the age of seventy-three years. There had been no evidence of a local recurrence or involvement of the opposite groin, but for a month he had been annoyed by a "burning sensation" on voiding and

rectosigmoid region are presented. The pressing need for earlier recognition of this type of cancer is again emphasized. Results obtained in terms of hospital deaths and survival rates are recorded, and fatal and significant, nonfatal complications are enumerated. Success obtained from a second resection in a very limited number of patients with recurrent or new cancer is noted. Although insufficient time has elapsed since treatment of the last patient to permit determination of the final figures on five-year survivals, attention is called to the fact that the trend of the immediate post-operative hospital death rate is definitely downward.

a urinary frequency of two or three times nightly. Microscopical examination of tissue obtained by a transurethral resection revealed prostatic cancer. His response to prostatic revision has been satisfactory, and he continues to work.

The survival periods for the entire group to June, 1948, are summarized in Table 5.

SUMMARY

Observations on a group of 100 consecutive patients with cancer involving the rectum and

REPEATED NEPHROTIC EPISODES WITH NORMAL URINE, SERUM PROTEIN AND CHOLESTEROL IN THE EDEMA-FREE INTERVALS*

HARRY A. DEROW, M.D.†

BOSTON

A PATIENT in whom the nephrotic syndrome appeared and disappeared on three occasions has been observed from 1933 to 1948. During each remission albuminuria and edema disappeared, and the serum protein and cholesterol values returned to normal. Only 3 similar cases have been located in the extensive literature on the subject. The details of this case including the many observations made over the period of fifteen years and a review of the relevant literature are the subject of this report.

CASE REPORT

M. C. (B.I.H. No. 18029), a 17-year-old boy, entered the hospital on April 17, 1933, because of swelling of the lower eyelids and over the sacrum. Until December, 1932, he had been well except for chronic eczema of the right hand. At that time swelling of the legs developed, later, swelling of the thighs and lower eyelids and over the sacrum was noted. Except for the edema, which had continued until admission to the hospital, there had been no symptoms or history of a respiratory tract or other infection or smoky or bloody urine.

Physical examination revealed a tall, pale, poorly nourished boy with definite puffiness of the eyelids and pitting edema over the sacrum but no edema elsewhere. The fundi were normal as were the throat, heart, lungs and abdomen. The blood pressure was 104/75. Examination of the urine showed a specific gravity of 1.035 and a large amount of albumin, but the sediment was normal. During the hospital stay of 1 week the urine specific gravity ranged from 1.018 to 1.035. Additional specimens showed doubly refractile bodies and an occasional white cell and cast. Phenolsulfonephthalein excretion was 55 per cent in 2 hours and 10 minutes after the intramuscular injection of 1 cc of the dye. Examination of the blood revealed a normal non-protein nitrogen, low serum protein and serum albumin and elevated serum cholesterol values (Table 1). During a 1-week stay in the hospital the albuminuria diminished to a minimal amount, and the edema entirely disappeared. After discharge on April 25 albuminuria decreased further, finally disappearing in June.

Routine physical examination on admission to the first-year class at Harvard College in September disclosed no edema. The urine had a specific gravity of 1.020 and was free of albumin and the sediment was normal. The blood pressure was 110/70. In June 1934 the findings were the same. At that time, blood chemical studies were normal (Table 1).

On October 17 the patient was admitted to the Stillman Infirmary of Harvard University because of malaise and anorexia, which had developed without antecedent infection.† Edema of the extremities had recurred. The urine showed considerable albumin, the specific gravity ranged from 1.014 to 1.028, and the sediment contained occasional red and white cells, casts and many cells with "fat globules." Blood chemical studies were similar to those in the first episode (Table 1). Toward the end of the first week of the infirmary stay the edema disappeared. Upon discharge on November 27, the patient was free of edema but showed massive albuminuria, hypoproteinemia and hypercholesterolemia.

*From the Medical Service, Beth Israel Hospital and the Department of Medicine, Harvard Medical School.

†Associate in Medicine, Harvard Medical School, visiting physician and head of Nephritic Clinic, Beth Israel Hospital.

‡I am indebted to Dr. Alfred E. Krane, of the Department of Hygiene, Harvard University, for data on the patient's condition during this episode.

During December marked edema of the eyelids, legs and sacrum recurred. Examination of the urine revealed massive albuminuria and a specific gravity of 1.024, and the sediment contained occasional red cells and casts.

He was readmitted to Stillman Infirmary from January 24 to February 1, 1935, with mild impetigo. The edema disappeared as the impetigo cleared. The albuminuria gradually diminished and finally disappeared in April.

Many examinations from May, 1935, to March, 1945, showed no edema. During this 10-year period the urine was normal except in February, 1936, when after a cold and sore throat a minimal amount of albumin and 2 or 3 red and white cells per high-power field in the sediment were noted. In May, 1937, postural albuminuria was found. In April, 1938, the patient suffered with streptococcal sore throat and in July because of acute suppurative appendicitis he underwent an appendectomy, neither of these infections was accompanied by albuminuria except for a minimal amount on the day after operation.

The serum proteins and cholesterol were normal throughout this remission (Table 1). In September, 1940, when he enlisted in the Army, and in April, 1943, when he entered officers' candidate school, urine examinations were negative.

On March 1 and 2, 1945, while overseas, he suffered with a boil on the wrist for which he was given 120,000 units of penicillin with prompt relief. Three weeks later generalized anasarca recurred. This gradually diminished with frequent intramuscular injections of mercupurin and intravenous infusions of blood plasma. On May 23 he still showed slight edema of the legs and was returned to this country. The edema of the legs persisted, and puffiness of the face and lower eyelids recurred each morning until August, when he was discharged from the Army with the diagnosis of "nephritis, chronic, glomerular, nephrotic stage, moderate, cause undetermined."

Frequent examinations of the urine during the early phase of this nephrotic episode showed massive albuminuria and erythrocytes. Massive albuminuria persisted, and the specific gravity ranged between 1.023 and 1.028. Blood chemical studies revealed hypoproteinemia, hypoalbuminemia, hypercholesterolemia and normal nonprotein nitrogen (Table 1). The blood pressure fluctuated around 120/80.

From August, 1945 to June 1948, the patient was free of edema. On August 7, 1945, examination of a single specimen revealed no albumin and a normal sediment; the specific gravity was 1.030. In January, 1946, seven consecutively voided urines collected according to a method described elsewhere‡ showed no albumin, cells or casts, the specific gravity ranged between 1.027 and 1.040. Chemical quantitation of albumin in these specimens of urine showed 3 to 7 mg per 100 cc, which is normal. At that time blood chemical studies revealed normal nonprotein nitrogen, total serum protein and serum albumin, the cholesterol was 356 mg per 100 cc. (Table 1). Physical examination was negative except for dry scaling lesions on the wrists. The blood pressure was 110/70. From June 10 to June 15, 1946, he was hospitalized because of a carbuncle of the finger, with lymphangitis of the forearm and axillary adenitis. Incision and drainage of the carbuncle and frequent intramuscular injections of large amounts of penicillin brought about prompt recovery. Examination of eleven consecutively voided specimens of urine showed no albumin, normal sediments and specific gravity between 1.006 and 1.032. Blood chemical studies were normal (Table 1). The blood pressure was 130/80. The scaling of the wrists was diagnosed as "atopic dermatitis" by a skin consultant. In September, 1947, during a follow-up visit, physical examination was negative except for a few scaling lesions on both wrists. The blood pressure was 118/70. Seven consecutively voided urine specimens§ showed no albu-

§I am indebted to Mr. William Wright, of the Medical Laboratory, John Hancock Mutual Life Insurance Company, Boston, Massachusetts, for these determinations.

min, with normal sediments, the specific gravity ranging between 1 023 and 1 028. In January, 1948, the patient was given frequent intramuscular injections of large doses of penicillin for a carbuncle on the neck, with prompt recovery. Urine examinations were not performed. Edema did not recur. In June during a follow-up visit, physical examination was negative except for very few scaling lesions on one wrist. The blood pressure was 120/80. Eight consecutively voided urines¹ showed no albumin, the sediments were normal, and the

siphilis, gold intoxication, renal-vein thrombosis,² lupus erythematosus⁴ and mercury poisoning^{5, 6}.

The course of the nephrotic syndrome in these conditions shows considerable variation. In some, edema and albuminuria disappear, and the blood proteins and cholesterol return to normal levels. In others, although albuminuria persists, the edema

specific gravity ranged between 1 018 and 1 029. Blood chemical studies were negative.

DISCUSSION

The nephrotic syndrome is characterized by massive albuminuria, hypoproteinemia, hypercholesterolemia and edema. It occurs most often in glomerulonephritis. Other causes are lipoid nephrosis, intercapillary glomerulosclerosis, renal amyloidosis,

continues with very little change, or it may decrease or even disappear for a time only to recur, it may also diminish gradually and disappear coincident with a decrease in albuminuria, development of impairment in renal function, hypertension and, later, renal insufficiency.

However, cases of repetitive nephrotic episodes with normal urine, total serum protein and cholesterol in the edema-free intervals have rarely been

observed Leiter,⁷ Fishberg⁸ and Wilson,⁹ in their wide experience with renal disease, have never observed a case of this type. In an excellent review of the literature Bradley and Tyson^{10, 11} did not describe such cases. Recently, a sixteen-year-old girl with petit-mal seizures was described¹² in whom the nephrotic syndrome appeared during the

rotic symptoms and signs to the time of writing.¹³ Addis¹⁴ recently described 2 cases in which the nephrotic syndrome appeared and disappeared on two occasions as follows:

Case B H, female, aged 25 — Edema and proteinuria found October 1923. Both went away in the autumn of 1924, but proteinuria and later edema reappeared in 1925

administration of tridione and disappeared upon withdrawal of the medication on three different occasions. Hypertension and microscopical evidence of hematuria were found during the second nephrotic episode, and elevation of the blood urea nitrogen to 47 mg per 100 cc was found in the third nephrotic episode. This report was published five months after recovery from the third nephrotic episode, and the patient had remained free of neph-

and continued until October 1925. No recurrence of either edema or proteinuria up to 1938.
Case P L, male, aged 7 — Edema and proteinuria lasted for less than a month in 1935, and both disappeared. Both returned in 1938. The edema quickly went, but the proteinuria did not disappear until 1940.
In my case reported above the first two nephrotic episodes, in 1933 and 1934-1935, developed without definite antecedent cause. It is possible, however, that the first two nephrotic episodes were related

to secondary infection of the eczematous lesions. The third episode in 1945 followed a boil on the wrist, but the patient had had other infections including a streptococcal sore throat and acute suppurative appendicitis in 1938, a carbuncle on a finger in 1946 and a carbuncle on the neck in 1948 without recurrence of the nephrotic syndrome. Although the evidence does not permit one confidently to relate infection to the recurrent nephrotic episodes this possibility should be explored in patients who exhibit this phenomenon.

In the case reported by Barnett et al.¹² the findings of hypertension and microscopical hematuria in the second nephrotic episode and elevation of the blood urea nitrogen in the third nephrotic episode suggest that those episodes were due to acute glomerulonephritis of short duration and precipitated by tridione. In my case reported above there was never hypertension or nitrogen retention. The finding of minimal hematuria in the second and third nephrotic episodes may mean that these episodes were due to acute glomerulonephritis. However, in nephrosis "an occasional red blood cell in a high power field of centrifuged specimen"¹⁵ may be seen. Addis¹⁴ found by his special technic that in his patients the rate of red-cell excretion was within normal limits and that in the few cases in which abnormal numbers were found succeeding counts showed few red cells or none.

Leiter⁷ recently pointed out that "it would be easy to overlook a slight albuminuria continuing between nephrotic episodes if one did not examine concentrated urine specimens carefully." In my case presented above, repeated examinations of concentrated specimens of urine during the intervals between the nephrotic episodes and after the last episode revealed no albumin except during the second remission (Table 1). During this ten-year period, thirty-nine urine examinations were performed, thirty-five showed no albumin, whereas four showed minimal amounts of albumin under the following conditions: after a cold and sore throat, during a test for postural albuminuria, and on the day after operation for acute suppurative appendicitis. In the cases described by Addis¹⁴ "the urinary evidence of a renal lesion disappeared only to recur at a later date."

The absence of continuous albuminuria between nephrotic episodes in my case reported above and in those of Addis¹⁴ and Barnett et al.¹² is not consistent with chronic glomerulonephritis. In the latter condition, although edema may fluctuate from time to time, the albuminuria is constant and continuous. The nature of the renal lesion "that comes and goes"¹⁶ in the case reported above and in the cases of Addis¹⁴ is unknown.

The details of this remarkable case were discussed with Dr. Henry A. Christian, who states that it is unique in his extensive experience and who has presented certain aspects of the case in his recent monograph on renal disease.¹⁷

SUMMARY

The pertinent data in a patient in whom the nephrotic syndrome appeared and disappeared spontaneously on three occasions are presented. During each remission, albuminuria and edema disappeared, and the serum proteins and cholesterol returned to normal values.

The relevant literature is discussed.

MEDICAL MILITARY SCIENCE

MAJOR ABRAM S BENENSON, U S A *

BOSTON

DURING the past two years, a new course has appeared on the curriculum of forty-nine American medical schools. "Medical Military Science" or "Military Medicine" is its title. The Army provides its instructors, and the medical school is its sponsor. The students taking this course will shortly be members of the medical profession. That profession deserves to be informed of the training the neophyte has received in this post-war version of the Medical Reserve Officer Training Corps (ROTC).

As in the past, military medicine is an elective course offered to the student body. It is a progressive course, through the four years of medical school, meeting one hour weekly. Students are of two categories: those who are pursuing it simply as an elective course, and those who are enrolled in the Reserve Officers Training Corps. The latter must meet rigid physical standards and sign a contract at the beginning of their third year to complete the course and to attend a summer camp for training for six to eight weeks during the summer recess, after completion of the second or third year. In return, they are paid a small stipend by the Government and, on satisfactory completion of the course, are offered a commission as a first lieutenant in the Medical Corps Reserve.

The course is designed to supplement the medical-school curriculum, which prepares the student for the practice of civilian medicine. The medical school teaches him the technics involved in providing ideal medical care for the individual patient, and indoctrinates him with the fundamentals of public-health organization and practices. Military medicine introduces the student to a broader concept of mass medicine, to the problems of the situation where the facilities of standard medical practice are overburdened — in short, to the approach that must be used to cope with a catastrophe. Although it is within the realm of possibility that war will be outlawed, catastrophes will always constitute a problem in the planning of medical care. To make the material generally pertinent, the presentation is usually based on the line of action to be followed in case of catastrophe or disaster — fire, flood, blast or war.

Intelligent medical service in a catastrophe can be rendered only by planned action, with consideration of personnel densities and exposure to hazards. Medical facilities will be weighted in favor of the larger city; preparations will be made for casualties where explosive materials are stored in a burning warehouse. Conversely, the potentialities of the

situation must be known, lest the rescuers themselves become casualties. Efficient disaster relief is not spontaneous, but is dependent on prior planning and organization. The best standard for a study of these considerations is found in the Army, since its medical department is designed to cope with the catastrophes produced by enemy action.

In the first year of the course in military medicine, the organization of the Army is studied from the point of view of its effect on the disposition, number and severity of the sick and wounded. Tactics are briefly considered from the point of view of their influence, adverse or beneficial, on the problem of providing medical care. With the medical problem thus established, the over-all medical organization is taken up, demonstrating the deployment of equipment, skills and personnel to cope with the actual and potential situation, together with the integrating mechanisms (chain of command) that maintain unity of objective together with co-ordination of effort.

In his second year, the medical student is beginning his contact with clinical medicine. In his course in military medicine, it is appropriate for him to begin to consider the professional details involved in provision of medical care in disaster relief. The scheme of evacuation of the patient from the catastrophe scene, with progressions of medical care from life saving to reconstruction and rehabilitative measures as he passes through the echelons of medical care, from the aid station, through the clearing station, to the evacuation and general hospitals, is developed. The modifications in this evacuation scheme, which brings definite treatment forward to the nontransportable patient, are discussed. The contrast with routine civilian professional care becomes manifest, in that professional service is rendered to a group rather than an individual patient and that this medical care is rendered by different groups of doctors rather than by one practitioner. Maintenance of teamwork requires administrative effort at various levels. This is discussed with respect to the intramedical integration, as well as the integration of the medical aspect with the total effort. The provision of medical supplies, when the drugstore and surgical-supply house are no longer available, becomes critical. The import of available supplies in the catastrophe situation, and the necessity for standardization, procurement, stockpiling and distribution and maintenance of equipment are considered. The value of standardized equipment is demonstrated by practical sessions in the application of triangular and roller bandages, and Thomas and other stock Army splint materials.

*Professor of military science and tactics, Tufts College Medical School.

to secondary infection of the eczematous lesions. The third episode in 1945 followed a boil on the wrist, but the patient had had other infections including a streptococcal sore throat and acute suppurative appendicitis in 1938, a carbuncle on a finger in 1946 and a carbuncle on the neck in 1948 without recurrence of the nephrotic syndrome. Although the evidence does not permit one confidently to relate infection to the recurrent nephrotic episodes this possibility should be explored in patients who exhibit this phenomenon.

In the case reported by Barnett et al.¹² the findings of hypertension and microscopical hematuria in the second nephrotic episode and elevation of the blood urea nitrogen in the third nephrotic episode suggest that those episodes were due to acute glomerulonephritis of short duration and precipitated by tridione. In my case reported above there was never hypertension or nitrogen retention. The finding of minimal hematuria in the second and third nephrotic episodes may mean that these episodes were due to acute glomerulonephritis. However, in nephrosis "an occasional red blood cell in a high power field of centrifuged specimen"¹⁵ may be seen. Addis¹⁴ found by his special technic that in his patients the rate of red-cell excretion was within normal limits and that in the few cases in which abnormal numbers were found succeeding counts showed few red cells or none.

Leiter⁷ recently pointed out that "it would be easy to overlook a slight albuminuria continuing between nephrotic episodes if one did not examine concentrated urine specimens carefully." In my case presented above, repeated examinations of concentrated specimens of urine during the intervals between the nephrotic episodes and after the last episode revealed no albumin except during the second remission (Table 1). During this ten-year period, thirty-nine urine examinations were performed, thirty-five showed no albumin, whereas four showed minimal amounts of albumin under the following conditions: after a cold and sore throat, during a test for postural albuminuria, and on the day after operation for acute suppurative appendicitis. In the cases described by Addis¹⁴ "the urinary evidence of a renal lesion disappeared only to recur at a later date."

The absence of continuous albuminuria between nephrotic episodes in my case reported above and in those of Addis¹⁴ and Barnett et al.^{12, 13} is not consistent with chronic glomerulonephritis. In the latter condition, although edema may fluctuate from time to time, the albuminuria is constant and continuous. The nature of the renal lesion "that comes and goes"¹⁶ in the case reported above and in the cases of Addis¹⁴ is unknown.

The details of this remarkable case were discussed with Dr. Henry A. Christian, who states that it is unique in his extensive experience and who has presented certain aspects of the case in his recent monograph on renal disease.¹⁷

SUMMARY

The pertinent data in a patient in whom the nephrotic syndrome appeared and disappeared spontaneously on three occasions are presented. During each remission, albuminuria and edema disappeared, and the serum proteins and cholesterol returned to normal values.

The relevant literature is discussed.

room is actually demonstrated, and culminates in a field exercise in which the students participate in the evacuation and simulated field medical treatment. The many veterans among the current medical classes find this type of training reminiscent of unpleasant combat experience, and, although the objective is radically different, the similarity to previous experience suggests to them unnecessary repetition. There is discussion on the advisability of converting this summer training from field-type to professional-type training, during which the student will learn the administrative and technical

factors involved in actual medical and surgical care of the Army sick and wounded.

Those who teach this course believe that the new physician who has completed a course in military medicine is that much better a physician. He is prepared to take a leading position in community defense plans, he is prepared to serve his country in or out of the armed force. He has demonstrated his willingness to make a sacrifice for the privilege of citizenship. It is possible that he will not be as adroit in litter drill as his father, but he is that much better a citizen and physician.

MEDICAL PROGRESS

ANTIBACTERIAL CHEMOTHERAPY (Continued)*

AVRAM GOLDSTEIN, M D †

BOSTON

Resistance

Priority for demonstration of the resistance of micro-organisms to specific drugs goes to Ehrlich,^{153 155} who was able to isolate strains of trypanosomes resistant to three distinct drug classes. Resistance, in his experiments, was shown to arise by repeated passage through low concentrations in vitro or in vivo, to be permanent once established and to be specific for each class of drug. Thus, organisms made resistant to triphenylmethane dyes remained sensitive to azo dyes and organic arsenicals.

Ehrlich foresaw that drug fastness was to prove a major clinical stumbling block and proposed the only two means available for avoiding the difficulty to eliminate *all* organisms as rapidly as possible, and to take advantage of the absence of cross-resistance by employing, when possible, drug combinations.^{1 164} The same conclusions are, of course, repeatedly arrived at today from studies based upon a far more advanced understanding of the nature of resistance.

Resistance to the antibacterial chemotherapeutics was first encountered on an important clinical scale after a few years of sulfonamide treatment of gonorrhea.^{156 159} A sharp drop in the cure rate was accompanied by the isolation of increasing numbers of sulfonamide-resistant gonococci.^{160 163} Subsequent experience, both in the laboratory and in the clinic, showed that drug-fast organisms regularly developed when an initially sensitive strain was grown in the presence of an antibacterial drug. This was true with the sulfonamides and penicillin,

but the most frequent and extreme cases of resistance occurred with streptomycin.¹⁶⁴⁻¹⁶⁹

Most workers are agreed that the development of resistance, like the chemotherapeutic action itself, is quite independent of the host. *It is not the patient but the bacteria that, under certain circumstances, become refractory to further chemotherapy.*

Resistance is encountered in two distinct forms. On the one hand a variety of bacterial species are relatively insensitive to the action of any one drug, and even among sensitive species more or less resistant strains are found. Detection of such resistant strains requires the use of very large inoculums, the drug then favoring survival of the less sensitive organisms.¹⁷⁰ One of the real disadvantages of streptomycin is the very wide range of sensitivity to its action displayed by organisms of every species.

On the other hand it has been frequently shown that resistant forms may arise *de novo* during contact of organism with drug. It was long an open question whether resistance of this kind arose through spontaneous mutation during the period of contact ("current mutation") or was to be attributed to a specific interaction of drug with bacteria. The outstanding work of Demerec¹⁷¹ now appears to have settled the question in favor of the former hypothesis, at least for *Staphylococcus aureus* and *Escherichia coli*. Mutations occurring in random fashion give rise to resistant variants, which are then favored by selection in the presence of a drug. Resistance to penicillin and the sulfonamides proceeds stepwise with selection at each step to yield populations of higher and higher degrees of resistance.^{73 165} This is explained by the postulated presence of several genes, mutation of any one pro-

This is combined with instruction in the practical first-aid measures that a second-year medical student should have in his armamentarium.

The catastrophe situation fosters the development of disease. In earlier wars the problems produced by disease and epidemic have exceeded medical capacity. In the last two years of the course, the advances of military preventive medicine that were successful in avoiding this eventuality in the recent war are presented. The methods that the Army has found of value in following the disease situation and in forestalling epidemics are discussed. Military preventive medicine encompasses all sanitary situations, from the most hazardous to the most salubrious, from the frozen Arctic to the tropical jungle. The student is indoctrinated with the basic principles involved in disease prevention and, guided by methods that have been found successful, is taught to improvise the solution fitting the particular situation in which he may find himself. The necessity and the means of enforcing the most rigid sanitary control in the catastrophe situation are stressed.

In these clinical years, while orthodox medicine, surgery and psychiatry are being presented, military medicine presents the modifications induced by the catastrophe situation. Therapy must be projected spatially as well as temporally. The teamwork impelled by the echelon system of medical care requires standardization of therapeutic procedure. Although the practice is repugnant to the traditionally individualistic physician, the welfare of the patient requires a limitation of procedures based on availability of equipment and personnel and the exigencies of the local situation. The concept of teamwork dictates that the plays be called in advance and that one man carry the ball just so far, passing it to his teammates who have been prepared to carry on. In medicine and surgery, the objective is the civilian ideal medical care. However, the disaster situation will often force the results to fall short of that objective, since masses rather than individuals are concerned, in the field rather than a scientifically designed operating theater. Still the recent war produced a medical record of which no member of the profession need be ashamed.

The psychiatric picture in the catastrophe situation is distorted by the disruption of normal habits, normal gratifications and psychic supports. The emotionally unstable may well be driven from the normalcy they cling to. The need for and value of preventive psychiatry and the feasibility of very early and mass therapeutic measures are demonstrated.

There are in addition unusual health hazards with which the military authorities are primarily concerned. Although diplomats may strive to eliminate the need, the medical profession must still be prepared to cope with the catastrophe produced by

nuclear fission and chemical agents—a continual threat by accidents, industrial or diplomatic. The medical management of these situations is discussed in the fourth year.

It may be seen that the medical ROTC course today is primarily professional. This is consistent with current military planning, in which emphasis is placed on the professional qualities of medical personnel. However, the student who completes this course is to be qualified to assume the position of a commissioned officer in the Army. To this end, a minimum of time is devoted to give the future medical officer enough knowledge to avoid the embarrassment experienced by many medical officers who received their commissions with no military training and entered active duty with the relatively high rank conferred on all medical officers. The ROTC student is taught to recognize the grade insignia of personnel of the armed forces, he is also taught the principles of military courtesy and command and of military law. The basic principles of military correspondence and administration are explained, dispelling the physician's impression of "red-tape." He is given enough instruction in map reading to provide terrain appreciation and orientation—a knowledge of practical value.

As a potential member of the Army Medical Department, he is instructed in what it has to offer him. Its history and evolution to its present pattern and what it has contributed to the knowledge of medicine are discussed. Its research methods and plans, the part each person plays in contributing to the store of knowledge by keeping medical records is explained, and what the services offer as a medical career are discussed.

The history of this country shows that the medical profession has been outstanding in its patriotism. Traditionally the doctor is an "educated" man, not only professionally but also generally. However, the medical student of the current day has rarely the time to ponder the problems that confront the country. In the course in military medicine, three hours during each year are devoted to a discussion of the currently confusing and difficult problem of national and international affairs, reminding the student that, even while he is in medical school, he still has obligations to his country.

The medical ROTC program has completed its first year at Tufts College Medical School. Despite a student body composed largely of veterans, there has been a real and increasing response to the program. Student comment has indicated that the participants in the program concur in the practical value to be obtained from such a course. One third-year student wrote, "This course should be 'advertised' as essential to freshmen."

Present summer-camp attendance required of enrolled students consists of a six-week period of training at Fort Sam Houston, Texas, during which the material covered in the medical-school class-

small animals (such as the mouse intravenous LD_{50}), chronic reactions are brought out by prolonged feeding or repeated injection into a variety of animals. Molitor's¹⁹¹ report on streptomycin is a classic study of acute and chronic toxicity in animals.

Unfortunately, as Marshall¹⁹³ points out, although animal toxicity may in a general way resemble effects in human beings, the correlation is by no means reliable, and toxic dosage, expressed in milligrams per kilogram, can rarely be translated from species to species. The wartime antimalarial program¹⁹⁴ brought this out for a considerable number and variety of drugs. Furthermore, reactions of the sensitivity type often cause the greatest difficulty in the clinic, and yet these are rarely observed in experimental animals. Caution is therefore necessary in the prediction of human toxicity from animal experimentation alone, although without question major toxic potentialities will be revealed in such studies.

Sulfonamides Sulfonamides display a variety of untoward effects, manifested by sulfadiazine and sulfamerazine to a lesser degree than by some of the earlier members of this group. These have been fully discussed by Janeway.¹⁹⁵ The major toxic manifestations of sulfathiazole, sulfadiazine and sulfamerazine are damage to the kidneys, interference with the normal production of leukocytes, and fever. The last two are evidently sensitivity phenomena, unpredictable, and often elicited by extremely small doses. The prevention of granulopenia has not been achieved, but the gravity of this condition has been considerably minimized by prophylactic control of secondary infection with penicillin.

The twofold effect upon the kidneys (crystalluria and toxic nephrosis) is closely dependent upon the drug dosage and certain other important factors. Crystalluria has long been recognized as a simple consequence of supersaturation of the urine, where these drugs and their acetylated derivatives are highly concentrated. All become increasingly soluble at an alkaline pH, a fact that provides the rationale for adjuvant alkalization, forcing of fluids to permit excretion of a reasonably dilute urine and frequent check on the urine pH and specific gravity. An interesting approach to this problem was proposed by Lehr¹⁹⁷ and also by Frisk and his co-workers,¹⁹⁸ who demonstrated that, as theory predicted, the solubility of one sulfonamide is almost independent of others present in the same solution — for example, a saturated solution of sulfathiazole will dissolve nearly as much sulfadiazine as an equal volume of water. It had long been known that most of the sulfonamides act similarly, and more or less additively against sensitive microorganisms. These facts are the basis of the suggestion that mixtures of sulfonamides invariably be employed, whereby the total dose is divided among three drugs. The mixture employed by Frisk, with

significant reduction in crystalluria, consisted of sulfathiazole, sulfadiazine and sulfamerazine in the proportions 37:37:26. Larger doses could be given and higher blood levels (of total sulfonamides) attained than otherwise, without supersaturating the urine with any of the three compounds or their acetyl conjugates. Whereas crystalluria is unquestionably reduced in experimental animals,¹⁹⁹ and in some clinical experiences,²⁰⁰ conflicting clinical reports have appeared.²⁰¹ One might raise the question whether it is wise to risk sensitizing patients to three drugs instead of one in view of the fact that patients reacting to sulfathiazole, for example, often tolerate sulfadiazine or sulfamerazine. Whether from the standpoint of over-all toxicity the use of mixtures is in fact superior to single-drug regimes remains to be proved in a statistically valid number of patients.

It is not clear whether the toxic nephrosis occasionally seen is closely related to the crystalluria, but, curiously enough, alkalization of the urine reduces the incidence of both.²⁰²

Penicillin Penicillin remains a pharmacologic curiosity because of its almost completely innocuous character. No toxic effects of the dose-related type have been reported, this is the more remarkable in view of the enormous number of persons (literally millions) who have received the drug. The lethal dose of penicillin cannot be determined since it is less toxic than any of the cations (sodium, potassium, calcium and so forth) with which it has been associated.²⁰³ Doses of several million units daily are regularly tolerated in the treatment of refractory diseases, but it must be observed that the "enormous" dose of 10,000,000 units daily represents only 6 gm. of penicillin G sodium, and only 0.5 gm. of the cation. On the other hand intrathecal injection may, and direct cortical application does, lead to convulsive phenomena of unknown mechanism with both penicillin²⁰⁴ and streptomycin.²⁰⁶

Sensitivity reactions occur in about 5 per cent of patients, usually as urticaria (which responds to antihistaminic drugs), dermatitis or drug fever.⁶¹ These appear most frequently with oil-and-wax mixtures, which are also prone to cause annoying local tissue reactions.²¹²⁻²¹⁴

Streptomycin Streptomycin, unfortunately, displays a serious toxic effect of the dose-related type — that upon the eighth nerve and vestibular apparatus.²¹⁵⁻²¹⁸

The relative infrequency of this injury in the therapy of acute infections suggests that duration of therapy (or total dose) is the crucial factor. The statistical incidence of the reaction is not easily assessed, since it often appears in mild and reversible form as a disturbance of hearing or equilibrium that may not be especially prominent while patients are bed ridden.²¹⁵ Moreover, a number of the reported cases occurred in persons suffering from

ducing about the same degree of resistance and successive mutations producing additive effects. Since a double mutation would be an extremely improbable event, Step 1 mutants become predominant before a second mutation results in establishment of Step 2 mutants, and so on. With streptomycin, however, the stepwise character is by no means regular, variants of extremely high resistance may arise at once from a sensitive parent strain.^{165 166 172} This fact is explained by the assumption that the several genetic factors vary in potency, since chance alone determines which will mutate, the result is an unpredictable irregularity in the degree of resistance. It follows that, with sulfonamides and penicillin, resistance can be controlled by reduction of the total number of growing organisms (since cell division favors mutation probability) to lower thereby the possibility of a Step 1 variant mutating again to Step 2. With streptomycin this is practically impossible since the first mutation of a sensitive organism may yield a highly resistant offspring. (A general review of the mutation problem was presented at the Cold Spring Harbor Symposium of 1946.¹⁷³)

Several investigators have shown that resistance only develops in actively growing populations,^{164 172 174} as one would expect on theoretical grounds. One type of resistance to penicillin, characterized by production of penicillinase, may be increased *pari passu* with a rise in penicillinase activity, by rapid growth and frequent subculture in the absence of the drug.¹⁷⁴ Grown in ordinary mediums in the absence of penicillin, such resistant organisms do not revert, but when they are supplied with special substrates, reversion to the previously sensitive condition occurs.¹⁰² It has never been shown that penicillinase meets the criterion for an adaptive enzyme, but exactly analogous findings regarding the appearance and disappearance of adaptive enzymes have been reported by Spiegelman and Reiner.¹⁷⁵ A theoretical approach to drug resistance, with emphasis on adaptation, is advanced by Hinshelwood,¹⁷⁶ and a conflicting point of view is presented by Sevag.³⁷

A study of streptococci of groups A, B and C, grown in penicillin, reveals that one bacterial group may differ from another of the same species, in the tendency to become drug-fast, the characteristics of the resistant forms and the permanence of resistance.¹⁷⁷ Resistant organisms arising through current mutation sometimes show a surprising tendency to revert upon removal of the drug.¹⁰¹ This is difficult to explain on a basis of back-mutation unless it can be shown why nonresistant forms would be favored in the absence of drug. The only evidence bearing on this is the finding that certain resistant strains have a slower growth and metabolic activity than the parent sensitive strain.^{78 104}

Except for the unique case of penicillinase-producing organisms, it is now generally accepted

that bacteria become drug-resistant by developing an alternate metabolic pathway, which by-passes the previously inhibited steps. How this could occur on a mutation basis is indicated by the fundamental studies of Beadle and his collaborators,¹⁸¹ who showed that the presence or absence of the enzyme mediating each metabolic step in *Neurospora* is controlled by a single gene. Appearance of a new enzymatic step circumventing that inhibited by a drug might thus arise from random gene mutations. Of unusual interest in this connection is the report of a *Neurospora* variant requiring sulfonamide for growth and inhibited competitively by PABA.¹⁸²

From the clinical standpoint the resistance problem offers the greatest drawback to the use of streptomycin. It has been shown repeatedly that organisms cultured from refractory patients after prolonged therapy prove resistant as compared with the original strain and that this development may occur with alarming rapidity,¹⁷⁹⁻¹⁸⁴ often carrying a disease quickly beyond control by the drug. This emphasizes the importance of frequently determining organism sensitivity and, so far as possible, increasing dosage to meet new thresholds.

If the concepts outlined above are correct there seems no sure method of avoiding drug fastness. "Frappet fort et frapper vite"¹⁸⁵ remains the only countermeasure. Mutation to resistance is unlikely to occur if multiplication of organisms can be stopped at once, and variants beyond the first step will almost certainly not appear. Prompt treatment with adequate dosage until an infection is entirely eliminated offers the best hope of control. Combined medication, suggested by some authors¹⁸³ and yet not generally employed, seems thoroughly logical since the few variants resistant to one agent can be controlled by the other before selection makes them the predominant type.

The appearance of streptomycin-requiring organisms has been reported by several investigators.¹⁸⁶⁻¹⁹⁰ These were avirulent for animals until streptomycin was administered, when fatal infection promptly ensued. Although it is not inconceivable that these facts may have clinical significance, the results cited were obtained *in vitro* and no authenticated case of therapeutic failure on this basis has yet been reported.

Toxicity

It is axiomatic that an effective chemotherapeutic is a compound of low toxicity that has shown a favorable chemotherapeutic ratio in experimental animals. Toxicity, broadly speaking, is of two kinds: one bears a definite relation to dosage, the other falls into the category of sensitivity phenomena, whose incidence and severity do not strictly depend upon the amount of drug administered. Either type may appear after brief or prolonged exposure to a drug. Acute reactions of the first kind are generally elicited in toxicity tests with

against infection when the animals were injected with pneumococci *after disappearance* of detectable plasma levels following a single dose of penicillin. This result may be explained in part by the recent findings^{233, 234} that penicillin levels in tissues and lymph persist for some time after plasma levels have disappeared.

In human beings gonorrhea has been cured by a single 15-mg dose of penicillin,²³⁵ and prevented by the single prophylactic administration of 1 or 2 gm of sulfathiazole.²³⁶ The meningococcus carrier state can be eradicated by a single dose of sulfadiazine.²³⁷

These observations must all be interpreted in relation to the duration of levels after the single

Refractory infections provide a more exacting test of the limits within which dose and frequency can be varied. In the treatment of subacute bacterial endocarditis, Loewe²⁴² reports that patients who fail to respond to prolonged therapy by the

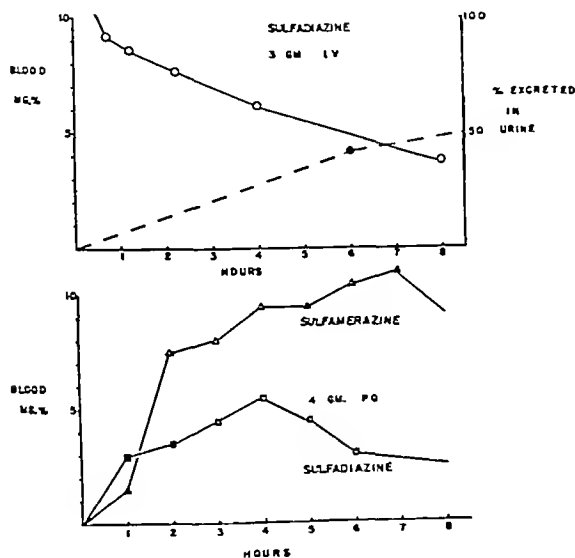

FIGURE 4

The upper half shows blood levels (solid curve) and cumulative urinary excretion (broken curve) of sulfadiazine after single intravenous administration (data of Sadock and Tredway²³³). The lower half shows blood levels of sulfadiazine and sulfamerazine after single oral administration (data of Bullock and Ratish²³⁹).

dose, the threshold level for the organism concerned and the response of the organism to varying periods of exposure to the drug. Every "single dose" is in reality a *course of treatment*, in which the pathogens are exposed to a changing drug level for a definite period (Fig 4-6). Increasing the size of the single dose not only raises the peak level but also prolongs the duration of suprathreshold concentrations. If an infection can be cured by short exposure of pathogens to a low drug concentration, effective cures will also, of course, be obtained through a wide range of higher doses and longer exposures. The experiments cited, then, represent a critical testing of the minimal requirements for cure, in infections caused by highly sensitive organisms.

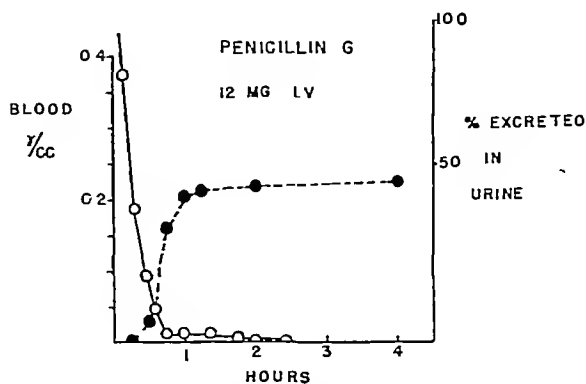

FIGURE 5 Blood Levels (Solid Curve) and Cumulative Urinary Excretion (Broken Curve) of Penicillin G after Single Intravenous Administration (Adapted from Data of Rammelkamp and Keefe²⁴⁰).

continuous route at a constant plasma level may be cured when the plasma penicillin level is raised. Priest and his collaborators²⁴³ also stress the importance of high and constantly maintained plasma levels in the management of this disease.

The fundamental studies of Eagle and his associates²⁴⁴ on time-dose relations in the cure of rabbit syphilis, demonstrate clearly that therapeutic efficiency depends upon maintenance of an effective blood penicillin level for a specified period of time.

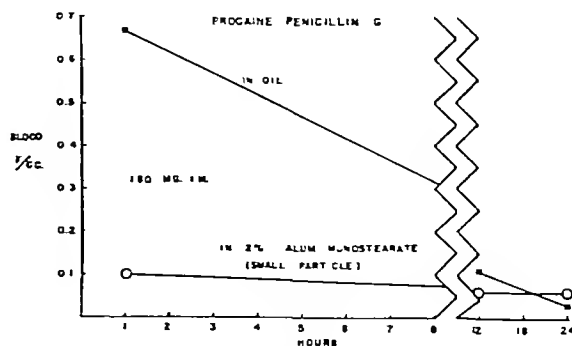

FIGURE 6 Penicillin Blood Levels after Single Intramuscular Administration of Two Very Reproductive Products (Data of Thomas et al.²⁴⁵).

The dose curing half the animals (CD_{50}) was lowest when repeated injections of small amounts of penicillin were given for a long time. The lowest CD_{50} was 360 units per kilogram of body weight, given as fifty injections (7.2 units per kilogram each) at

infectious disease of the central nervous system so that the drug could not surely be implicated. In any event the tendency has been, when possible, to avoid administering streptomycin for longer than a few weeks.²¹⁹ In the treatment of chronic infections analogy to the arsenicals might suggest rest periods, but this is illogical because it would favor the development of drug resistance. The problem appears to lack a practical solution, the nature of the remarkable specific affinity for a particular group of nerve cells²²⁰ is not understood, and the clinician is left little choice but to weigh the risk of prolonged treatment against its possible value and to warn the patient of the hazard.

In the therapy of urinary-tract infection, which constitutes one of the major indications for streptomycin, advantage should be taken of the enhanced potency of the drug in alkaline solution, chemotherapy should be preceded and accompanied by alkalinization procedures.²²¹ By increasing the potency of each microgram of streptomycin excreted into the urine one is enabled to reduce the systemic dosage to a point where the dangers of toxicity are distinctly lessened.

The use of streptomycin is also attended by the usual variety of sensitivity reactions,²¹⁸ including contact dermatitis among physicians and nurses who handle it frequently.²²²⁻²²³ Sensitivity may be ascertained by patch tests or intradermal inoculation, caution is indicated in the latter procedure by the report of a recent nearly fatal case in a hypersensitive person.²²⁴ One might observe that sensitivity reactions to drugs in general are among the least understood subjects in pharmacology. Though neglected in the past, they comprise a potentially fruitful field for joint study by pharmacologist, immunologist, physical chemist and clinician.

PHARMACODYNAMICS

Question of Drug Levels

It is generally agreed that the practical aim of chemotherapy is to administer a drug in such a way that optimal in vitro concentration will be maintained at the locus of infection, continuously and until infectious organisms are entirely eradicated. This implies that all measures employed will be designed to maintain an effective drug level in close contact with the bacterial cells.

Recently the importance of drug levels, especially in the plasma, has been questioned, particularly by Marshall.¹⁹³ That certain infections can be cured despite undetectable or negligible blood levels is undeniable, especially with drugs that are selectively taken up or irreversibly bound by parasite or tissue proteins. In the arsenic-bismuth treatment of syphilis, for example, cure is more dependent on total dose than on concentration, and the frequency of

administration is not highly critical.²²⁵⁻²²⁶ Likewise, in antimalarial therapy, some drugs are so highly concentrated in certain tissues that plasma levels are insignificant by comparison¹⁹⁴; yet even with quinacrine, which has a high tissue-plasma ratio, Shannon²²⁷ found good correlation between plasma levels and clinical response. Certainly, no generalization will apply to all drugs, the question here is to what extent plasma drug levels are important in antibacterial chemotherapy.

Little doubt has been expressed that the sulfonamides act at a definite threshold concentration determined by the sensitivity of each bacterial strain and species, and the same observation is true of the *bacteriostatic* action of penicillin and streptomycin. Eagle and Musselman⁷²⁻⁷³ recently demonstrated a paradoxical effect whereby certain streptococci and staphylococci show a *decreased death rate in vitro* at very high penicillin concentrations. It was suggested that too much penicillin might prove harmful in infections caused by these organisms. However, the clinical importance of the "paradoxical phenomenon" can be questioned, since bacterial growth is presumably inhibited through the whole range of concentrations in which the paradoxical *bactericidal* effects are observed.

Some early workers cited the increased sensitivity of growing cells to the killing action of penicillin as a rationale for giving the drug intermittently, levels would fall repeatedly, and the bacteria would enjoy brief periods of growth, during which they would again be subject to the bactericidal effect of the drug. Here again, the importance of bacteriostatic action was overlooked. To release a dangerous pathogen from effective growth inhibition so that it can multiply and be killed is like releasing a petty criminal from jail in the hope that he will commit murder and become subject to electrocution.

Actually, the argument was *post hoc* reasoning in an attempt to explain why intermittent injection, with zero plasma levels for about half the time, was so outstandingly successful in the control of clinical infection. It has been shown that organisms removed from exposure to penicillin do not actually resume growth for several hours⁷⁴⁻⁷⁶ — a fact that goes far to explain the efficiency of an intermittent schedule.

Sweeping generalizations are sometimes made on the basis of the fact that in animal or human infection it is often possible to reduce the frequency of administration of a chemotherapeutic without loss of efficiency. For example, pneumococcal and other infections in mice have been cured by a single large dose of penicillin in place of repeated smaller doses.²²⁹⁻²³⁰ Similarly, guinea pigs can be protected against lethal tuberculous infection if streptomycin is administered as a 25-mg dose, whether that amount is given daily, or once in five days.²³¹ In a well designed experiment²³² rats were protected

against infection when the animals were injected with pneumococci *after disappearance* of detectable plasma levels following a single dose of penicillin. This result may be explained in part by the recent findings^{232, 234} that penicillin levels in tissues and lymph persist for some time after plasma levels have disappeared.

In human beings gonorrhea has been cured by a single 15-mg dose of penicillin,²³⁵ and prevented by the single prophylactic administration of 1 or 2 gm of sulfathiazole.²³⁶ The meningococcus carrier state can be eradicated by a single dose of sulfadiazine.²³⁷

These observations must all be interpreted in relation to the duration of levels after the single

Refractory infections provide a more exacting test of the limits within which dose and frequency can be varied. In the treatment of subacute bacterial endocarditis, Loewe²³² reports that patients who fail to respond to prolonged therapy by the

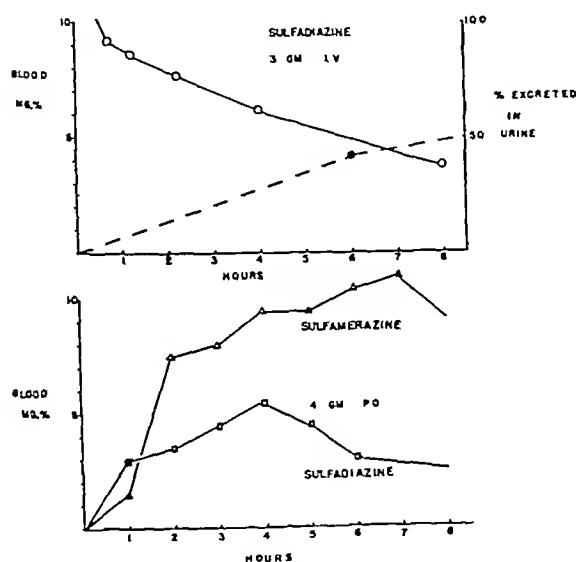

FIGURE 4

The upper half shows blood levels (solid curve) and cumulative urinary excretion (broken curve) of sulfadiazine after single intravenous administration (data of Sadusk and Tredway²³³). The lower half shows blood levels of sulfadiazine and sulfamerazine after single oral administration (data of Bullock and Ratish²³⁸).

dose, the threshold level for the organism concerned and the response of the organism to varying periods of exposure to the drug. Every "single dose" is in reality a *course of treatment*, in which the pathogens are exposed to a changing drug level for a definite period (Fig 4-6). Increasing the size of the single dose not only raises the peak level but also prolongs the duration of suprathreshold concentrations. If an infection can be cured by short exposure of pathogens to a low drug concentration, effective cures will also, of course, be obtained through a wide range of higher doses and longer exposures. The experiments cited, then, represent a critical testing of the minimal requirements for cure, in infections caused by highly sensitive organisms.

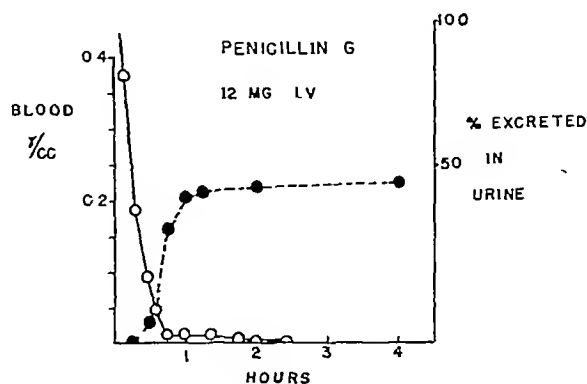

FIGURE 5 Blood Levels (Solid Curve) and Cumulative Urinary Excretion (Broken Curve) of Penicillin G after Single Intravenous Administration (Adapted from Data of Rammelkamp and Keefer²⁴⁰)

continuous route at a constant plasma level may be cured when the plasma penicillin level is raised. Priest and his collaborators²⁴² also stress the importance of high and constantly maintained plasma levels in the management of this disease.

The fundamental studies of Eagle and his associates²⁴¹ on time-dose relations in the cure of rabbit syphilis, demonstrate clearly that therapeutic efficiency depends upon maintenance of an effective blood penicillin level for a specified period of time.

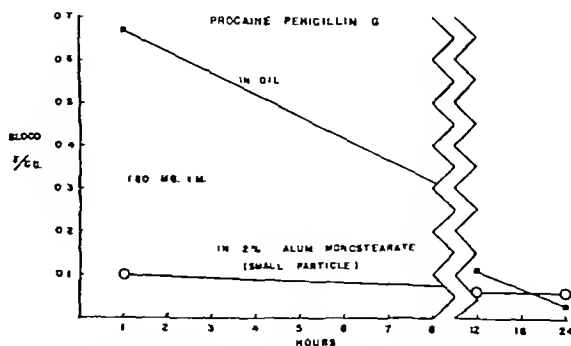

FIGURE 6 Penicillin Blood Levels after Single Intramuscular Administration of Two Neo Repository Products (Data of Thomas et al.²⁴³)

The dose curing half the animals (CD_{50}) was lowest when repeated injections of small amounts of penicillin were given for a long time. The lowest CD_{50} was 360 units per kilogram of body weight, given as fifty injections (7.2 units per kilogram each) at

four-hour intervals. Increasing or decreasing the interval, or reducing the number of injections with the same interval, had the effect of raising the CD_{50} —that is, more penicillin was required for cure.

The clinical counterpart of these studies is embodied in the report of Schwemlein et al.²⁴⁵ on the results of penicillin therapy of syphilis, with and without artificial fever, in large groups of patients treated according to different schedules. The results, which confirm the synergistic action of artificially induced fever, are also pertinent to the present discussion. Assuming the various treated groups to be comparable, the data have been tested for statistical significance, with the following results: when a total of 720 mg (1,200,000 units) was administered over one and a fourth and seven and a half days (both groups with accessory fever) to patients with primary syphilis, there was no significant difference in the cure rate, comparison of the same schedules in patients with secondary or relapsing syphilis gave a marked advantage to the longer schedule. It is obvious, as had previously been recognized, that early syphilis responds more easily than the longer established types. In such easily eradicated infections both the dose and the duration of treatment were probably more than adequate even in the one-and-a-fourth-day schedule.

Examining the combined cure rates for primary, secondary and relapsing cases, one finds that the 720-mg schedule is equally effective whether spread over seven and a half or three and three-fourths days but produces fewer cures when the length of treatment is cut to one and a fourth days. Furthermore, although 15 gm is more effective than 6 gm given in a single day, it is distinctly less curative than 720 mg over three and three-fourths days. Comparing doses given over the same seven-and-a-half-day period, there is a progressive decline in the cure rate from 720 to 180 mg.

These results refute the hypothesis that cure depends largely on the total dosage, regardless of the duration of treatment. Repeated small doses, sufficient to maintain fairly constant effective blood levels for three and three-fourths days, proved more effective than twenty times the same total dose administered in a single day. The data suggest that, provided a certain minimum blood level and duration of treatment are exceeded, treponemas can be reliably eradicated within a considerable range of reciprocal variation in both these factors.

Critical re-examination of the need for constant plasma levels has contributed to knowledge of actual minimum chemotherapeutic requirements in human disease. This is especially important in the use of streptomycin, excessive administration of which causes an unnecessarily high incidence of toxicity. This drug may be given less frequently

and in shorter courses than had been thought necessary without reduction of cure rate in a number of infections.²⁴⁹

Nevertheless a wholly negative attitude toward plasma levels does not seem justified. The whole body of in vitro evidence showing the intimate dependence of growth-inhibition and killing rates upon drug concentration cannot be dismissed, nor should the established dangers of inadequate levels be overlooked in the search for the dosage schedule that will just exactly cure. Unless the immediate environment of the pathogenic organisms can be sampled (as in the urinary-tract infections) the plasma level remains the only indication of the probable drug concentration to which they are exposed.

Maintenance of Drug Levels

The establishment and maintenance of an effective drug level depends upon the following factors: dosage, and frequency of administration, rate of absorption from the drug depot, wherever established, rate of drug inactivation, if any, within the body, extent of binding to plasma and other tissue proteins, and rate of excretion. Ideally, a chemotherapeutic should be slowly but completely absorbed by the oral route, not appreciably inactivated in the body, and slowly excreted. It should not be bound to nontarget* proteins to an extent that would reduce its free concentration below that desired. Pharmacodynamic properties may be improved by independent variation of any of the above factors toward the ideal, thus, absorption may be slowed, excretion blocked, and so on.

Sulfonamides

The sulfonamides present no serious pharmacodynamic problems. Sulfamerazine comes close to the ideal in all respects, oral administration of a 1-gm maintenance dose every six to eight hours proving adequate to maintain a fairly constant bacteriostatic level of the order of 8 mg per 100 cc, and sulfadiazine, requiring ingestion every four or six hours, is not inconvenient, although levels will fall during the night if medication is stopped. Large priming doses are needed with all the sulfonamides to establish a higher plateau level than could be reached by simple repetition of the maintenance dose from the start.^{195 238 249 246-250} Figure 4 shows (upper portion) the rate of disappearance of sulfadiazine from the plasma after intravenous administration and its simultaneous appearance in the urine. The lower portion of Figure 4 shows the typical course of the plasma-level curves for sul-

*Proteins of various tissues including the plasma in contradistinction to those of the parasite.

fadiazine and sulfamerazine after oral administration.

High local concentrations in the gastrointestinal tract are made possible through molecular modifications resulting in decreased absorption (sulfaguanidine and sulfathiadiazole²⁵¹) or very slow release of active drug (sulfasuxidine and sulfathalidine). High levels for combating localized infection in the urinary tract are automatic, so to speak, even when dosage is small and blood concentrations low, by virtue of the quantitative excretion of these drugs by the kidneys. A number of new sulfonamides have been investigated,²⁵²⁻²⁵⁵ and some whose chief virtue is high solubility have been tested in the clinic.²⁵⁶⁻²⁵⁷

Penicillin

Penicillin presents the problem of poor absorption by mouth, rapid absorption from intramuscular depots and an extremely rapid renal excretion, resulting in fluctuating levels with high peaks and deep valleys.^{240-253, 259} Figure 5 illustrates the rapid disappearance of penicillin from the plasma after intravenous administration and its simultaneous appearance in the urine. To overcome these serious deficiencies and devise some means of maintaining fairly constant levels with a modicum of comfort to the patients has been the aim of considerable research. It was early shown that oral administration of three to five times the usual intramuscular dose would yield comparable levels.²⁶⁰⁻²⁶¹ The belief that gastric acidity was largely responsible for inactivation by the oral route has been generally discarded for lack of evidence,²⁶² and simple administration every three hours of at least 60 mg (100,000 units) by tablet proves effective, though uneconomical. Results of treatment by this route of several hundred cases of gonorrhea compared favorably with those generally obtained when penicillin is given intramuscularly.²⁶⁰ The oral route, however, is contraindicated in the treatment of serious infections because absorption is, at best, irregular and unpredictable.

Early efforts were directed toward slowing absorption from an intramuscular depot by such crude means as chilling the site or injecting epinephrine, but the first method generally employed was the intramuscular injection of a large amount of penicillin in a mixture of peanut oil and beeswax (Romansky).²⁶³ A single dose of 180 mg (300,000 units) produces detectable levels for as long as twenty-four hours.²⁶⁴ The injections, however, may be painful and lead to a higher incidence of local and allergic reactions than with aqueous solutions.²⁴²

The principle embodied in the peanut-oil-beeswax mixtures has led to the development of several other so-called "repository" products.²⁶⁵⁻²⁶⁶ Loewe²⁶⁷ obtained results that compared favorably with the Romansky formula, using a water-soluble

preparation of penicillin in gelatin and dextrose. It was reported that a large number of insoluble metallic salts of penicillin released the active drug at a slow rate from intramuscular depots,²⁶⁸ and complexes with cationic dyes had the same effect. A compound consisting of a mol of penicillin combined with a mol of procaine was shown to act similarly. This material, which is now on the market in several forms, when suspended in an oily vehicle, was shown to produce detectable levels for longer, and in a higher proportion of patients, than the Romansky formula.²⁶⁹⁻²⁷⁰ Herrell and his associates,²⁷¹⁻²⁷² employing procaine penicillin suspended in sesame oil, report reliable prolongation or levels up to thirty hours after a single 180-mg (300,000 units) injection. These investigators express the view that the procaine confers an anesthetic effect²⁷³ and also, presumably, an antihistaminic one, since allergic reactions are so rare, even among patients previously reacting to ordinary penicillin. Similar results have been obtained by other workers,²⁷⁴ with aqueous suspensions of procaine penicillin. In a well controlled study of six repository products, Thomas and his collaborators²⁴¹ have shown that the most favorable results are obtained with procaine penicillin in peanut oil with aluminum monostearate. The particle size is critical, a striking advantage of 5-micron over 50-micron particles being observed. With the small particle size a single injection of 180 mg resulted in levels above 0.018 microgm (0.03 units) per cubic centimeter in 86.7 per cent of the subjects after four days. Figure 6 shows the markedly prolonged plasma levels resulting from the single administration of two different repository preparations by the intramuscular route.

It should be clear that the repository method will be satisfactory for the treatment of infections requiring relatively low penicillin levels. Unfortunately, the stress that is placed upon duration of detectable levels directs attention away from the shape and height of the plasma-level curve during the whole period between injections. With the earlier repository preparations peak levels were rather low so that in grave infection requiring a high penicillin level it was more reliable to depend upon intermittent aqueous injections or continuous intramuscular or intravenous infusion. The latter method carried with it the difficulty of local phlebotrombosis, but the assurance of an unvarying, high plasma level.²⁷⁵ Thrombosis is attributed to thromboplastic effects of the drug *in vitro*,²⁷⁶ but this has been disputed.²⁷⁷ It is too early to say whether the favorable properties of the newer repository preparations will allow one to establish and maintain high constant levels, but this seems a likely possibility.

In the treatment of localized infections much may be gained from a local drug level higher than would result from simple equilibrium with the

plasma. Such levels can be established in infections of the skin,²⁷⁸ oral and other mucous membranes,²⁷⁹ paranasal sinuses, pulmonary tree, and other sites, by direct topical application. An interesting development along these lines is the use of aerosol or dust inhalations of small-particle size in the treatment of pulmonary, tracheobronchial and sinus infections.²⁸⁰⁻²⁸⁶ Concentrations thus established in the pulmonary tissues of animals are several times higher than those in the plasma.²⁸⁷ On the other hand the finding of definite plasma levels after aerosol or dust therapy qualifies the method as a convenient and generally useful one in systemic penicillin therapy. High drug concentrations in the urine are again attained willy-nilly as a consequence of the rapid quantitative excretion of penicillin by the kidneys.

Another approach to the maintenance of constant plasma levels has taken the obvious direction of

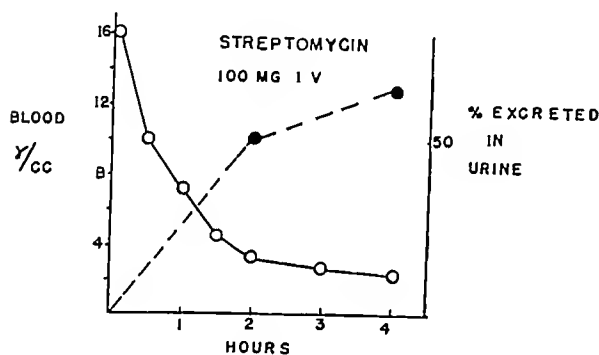

FIGURE 7 Blood Levels (Solid Curve) and Cumulative Urinary Excretion (Broken Curve) of Streptomycin after Single Intravenous Administration (Adapted from Data of Adcock and Hettig²⁸⁵)

attempts to slow the renal excretion of penicillin. The renal plasma clearance is found to be between 755 and 1120 cc per minute,²⁷⁵ and by another investigator²⁸⁸ about 560 cc per minute, figures that approximate the total blood flow through the kidney. These values are to be compared with 12 to 34 cc per minute for sulfadiazine and 4 cc for sulfamerazine.²⁸⁹ Thus, about 80 per cent of penicillin excretion is via the tubules, a fact that early suggested that other tubule-excreted compounds might act as blocking agents. Benzoate (excreted as hippuric acid), p-amino-hippuric acid and diodrast have all been shown to diminish the clearance of penicillin and thereby to raise the average plasma level.²⁹⁰⁻²⁹¹ Water and salt restriction enhance this effect,²⁹² presumably by diminishing the effective renal blood flow, combinations of these methods have succeeded, somewhat irregularly, in increasing plasma levels as much as fourfold to eightfold. However, fluid restriction seems undesir-

able in febrile infections, and some of the compounds employed are not wholly innocuous.

A more subtle method made its appearance with the discovery by Beyer and his associates²⁹³ that a sulfone compound, 4'-carboxyphenylmethanesulfonanilide (caronamide), blocked the tubular excretion of penicillin, reducing plasma clearance to the glomerular rate. The substance interferes with the tubular transport mechanism but does not affect the clearance of a variety of compounds excreted by glomerular filtration.²⁹⁴ Caronamide itself, although it acts specifically upon the tubules, is excreted solely by the glomeruli.²⁹⁵ Clinical experience has shown that ingestion of 2 to 4 gm every three hours is well tolerated by most patients. No case of severe toxicity has been reported,²⁹⁶ although gastric intolerance occurs not infrequently.²⁹¹ The average penicillin plasma level is raised twofold to sevenfold, the duration of detectable levels after a single intramuscular dose of penicillin is appreciably extended, and in general the response to 60 mg (100,000 units) of penicillin approximates that usually seen to 180 mg.²⁹¹⁻²⁹⁴ In aged persons the normal clearance of penicillin is below the average, and caronamide is effective in smaller doses than in younger subjects.²⁹⁷

The great concern about rapid loss of penicillin in the urine originated in the days when the drug was scarce and dosage had to be minimal. The tendency in many clinics today is toward use of very much larger routine doses than had been originally recommended. Should the new repository preparations fulfill their present promise it is quite possible that adequate control of most infections will be achieved by proper choice of the interval at which large doses of such preparations are injected. The use of adjuvant medication of the caronamide type would then be rendered unnecessary.

Streptomycin

From the pharmacodynamic standpoint the properties of streptomycin lie midway between those of the sulfonamides and penicillin. It is practically unabsorbed by the oral route but is not destroyed in the gastrointestinal tract,²⁹⁸⁻²⁹⁹ the convenient route for systemic therapy is thus barred, but employment against enteric pathogens is made possible.³⁰⁰⁻³⁰¹ When the drug is administered intramuscularly the plasma-level curve falls more slowly than that of penicillin, the slow fall being related to the low renal clearance of 30 to 80 cc per minute.²⁹⁹⁻³⁰²⁻³⁰³⁻³⁰⁵ The declining slope of the plasma-level curve indicates a permissible interval of four to six hours between doses. Figure 7 shows the disappearance of streptomycin from the plasma and its appearance in the urine after intravenous administration. An interesting mathematical treatment enabling one to predict plasma-level and time relations with remarkable accuracy, not only for streptomycin but also for other drugs, has been

formulated by Boxer and his co-workers³⁰⁶ With streptomycin the wide variation in thresholds of different organisms, and the real importance of maintaining effective levels to combat the threat of drug fastness should dictate a flexibility of dosage and interval based upon expected levels and checked frequently in each patient

The various methods of topical administration for high local concentrations are just as applicable here as with penicillin. In addition very large doses may be given by mouth in the treatment of intestinal disease caused by gram-negative bacteria or for preoperative sterilization of the bowel

(To be concluded)

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 35041

PRESENTATION OF CASE

A forty-six-year-old masseur was admitted to the hospital complaining of intermittent fever

Four months before admission he developed bronchopneumonia and was ill for about three weeks, with a temperature up to 102°F, moderate cough without bloody sputum and slight diarrhea. He received sulfadiazine for one week without benefit and then penicillin. While he was on the latter therapy the course slowly improved. He became asymptomatic during the next few weeks but was unable to regain the 25 pounds he had lost during the acute illness. There was a marked change in his muscular appearance, with definite atrophy, particularly of the muscles of the arms and shoulders. Two and a half months before admission he noted listlessness, easy fatigability and an afternoon temperature to 100.5°F, followed by profuse sweating. There were no night sweats, cough or pain. Febrile rises occurred periodically.

He had had nocturia (twice a night) for many years. The patient's wife stated that he had frequent nausea, vomiting and chest pain. For about five years he had been troubled by migratory ar-

thralgias. On several occasions he had periarticular swelling of the hands and knees, suggesting urticaria. The arthralgias were readily relieved by aspirin, and medical aid was not sought.

Physical examination was negative except for slight pallor.

The temperature was 99°F, the pulse 100, and the respirations 20. The blood pressure was 132/82, systolic, 82 diastolic.

Examination of the blood disclosed a white-cell count of 8600, with 73 per cent neutrophils, 22 per cent lymphocytes, 1 per cent mononuclears and 4 per cent eosinophils. The hemoglobin was 11.8 gm. The specific gravity of the urine ranged between 1.002 and 1.006, with a +++ or ++++ test for albumin. On microscopical examination occasional red and white cells and granular, cellular and hyaline casts were found in the sediment.

The sedimentation rate was 13 mm in one hour. The nonprotein nitrogen was 18 mg, the calcium 8.8 mg and the phosphorus 3.3 mg per 100 cc. The alkaline phosphatase was 3.7 units. A cephalin flocculation test was + in twenty-four and ++ in forty-eight hours. The total protein was 6.95 gm, with an albumin-globulin ratio of 1:1.8. Blood cultures were negative. The brucellergen skin test was negative. Tuberculin (OT) was positive in dilution of 1:100 in twenty-four hours, with a 3-cm to 4-cm area of erythema and induration and some pruritus. An electrocardiogram was normal. The basal metabolic rate was +10 per cent.

An x-ray film of the chest was normal. A film of the left knee showed slight hypertrophic changes about the articular surfaces consistent with a slight degree of osteoarthritis. On Graham test the gall bladder filled with well concentrated dye and contained a rounded, nonopaque shadow consistent with calculus. A gastrointestinal series demonstrated a constant narrowing in the prepyloric region for a distance of 3 cm. In the center of the narrowed portion a constant collection of barium,

measuring 1 cm in diameter, was seen. A plain film of the abdomen demonstrated that the right renal shadow was larger than the left.

The hospital course was essentially afebrile, and the patient was discharged seven days after admission. A short time later he was admitted to another hospital, where x-ray studies failed to demonstrate the prepyloric lesion previously found. An intravenous pyelogram and gastric analysis were negative. A gastrointestinal series one month later suggested a duodenal ulcer, with spasm of the antrum. Following discharge the course at home consisted of rather persistent fever and fleeting severe joint pains. There were no objective joint changes, however. Weight loss was progressive. Bloody diarrhea, persistent vomiting and oliguria appeared. He did not become comatose. Joint pains and fever continued up to the end. He died about one month after leaving the hospital.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM W. BECKMAN: The tuberculin test was positive in dilution of 1:100. I assume that it was negative in higher dilutions.

DR TRACY B. MALLORY: I do not believe we know.

DR BECKMAN: Obviously I do not know what this man had. If one reads the present illness, the past history and the routine laboratory work and sets them apart from the rest of the record, one has a history of five years' nocturia (twice a night), and a few months of anemia, albuminuria and pallor, symptoms that seem to have been precipitated by acute infection, and one forms the first impression that this patient was suffering from exacerbation of underlying nephritis, precipitated by acute infection. When one goes on a little further to try to distinguish the nature of the renal disease (I am sure that he must have had some kind of renal disease), it becomes less clear what kind it was. He obviously had some diffuse constitutional disease that gave rise to fever, weight loss, general malaise and so forth. That could be part of the nephritis, although fever is an unusual symptom in that disease. He also seemed to have had some kind of skeletal disease. The changes in his muscular system did not prove as striking on physical examination as one would have expected on reading the history. At any rate, he had some kind of disease that gave him joint pains off and on in the past and ultimately during the final illness were an important feature. Apparently in this hospital no one saw objective signs of joint disease, at least, there is no record. I do not see how one can make a definite diagnosis of the type of joint disease. I suppose we can say that it was consistent with rheumatoid arthritis, but that means nothing. Perhaps the x-ray films will help us decide what the osteoarthritis is. We do not know what symptoms led to the taking of the gastrointestinal series, but

there was some abnormality. Of course, he did have diarrhea and later bloody diarrhea.

DR STANLEY M. WYMAN: I did not plan to show this film. It is not a very impressive picture of arthritis.

DR BECKMAN: It certainly is not—probably normal knees.

DR WYMAN: The films of the chest show questionable diminution in size of the right middle lobe and some increased linear markings, consistent with an old, chronic process with fibrosis. The lung fields are otherwise clear. The heart shadow is not remarkable for a patient of this age. The findings in the gastrointestinal tract as recorded by these films consist of an area of narrowing in the prepyloric and distal antral region, it is seen on all the films. This area on a second examination appears to contain a crater measuring perhaps 1 cm in diameter. The gall bladder shows a small, round, radiolucent shadow consistently on four separate films. The spleen may possibly be a little larger than usual. The right kidney is of normal contour. The left kidney is partially obscured by barium but appears smaller than normal, much like a shrunken kidney. I can see no unusual areas of calcification, no unusual masses and no evidence of destruction of bone.

DR BECKMAN: I suppose at least we can make the diagnosis of a gallstone, but that hardly seems to explain the situation.

This patient had three distinct systems—renal, circulatory and gastrointestinal—involved in this disease, and I suppose the object of this discussion is to try to think of ways in which one can explain most of the symptoms—not all of them—by one diagnosis. I do not know that I can. When one reads the history of the present illness, one thinks of chronic nephritis, but the lack of any nitrogen retention is very much against that. Chronic pyelonephritis or chronic glomerulonephritis would not cause as many symptoms as this did. So I do not believe that either of those diagnoses need be entertained too seriously. I do not know how one can absolutely rule them out, although I would expect nitrogen retention if the patient was as sick as this from chronic pyelonephritis or chronic glomerulonephritis. One has to give consideration to the fact that at the onset of the illness he had received sulfonamides, which are known to cause a type of renal lesion. Dr Mallory has taught us to believe lower-nephron nephrosis is reversible so one would anticipate that the patient would either have died sooner or have been better by this time.

I was interested in the x-ray film of the knees because I thought if the patient had rheumatoid arthritis, one would have to entertain the possibility of amyloid disease, which is frequently a complication of rheumatoid arthritis and in which some people say, at any rate, albuminuria and other evidence of renal disease can occur without much

nitrogen retention and without high blood pressure. This man did not have high blood pressure in the one recording we have. I have no way of ruling out amyloid disease. It would explain a number of the symptoms and possibly the fact that the spleen was in the upper limits of normal by x-ray study, even if not palpable. There is no way to establish that diagnosis, however, it is just something one mentions tentatively.

Of course there is always periarteritis nodosa to be thought of with this sort of symptomatology. It produces gastrointestinal symptoms, skeletal symptoms and renal disease. It has many different kinds of manifestations, and I do not see how one can make the diagnosis clinically, unless there is asthma or a high eosinophil count in conjunction with these symptoms. In 1939, when Dr Short was making out the diagnostic file for the Arthritis Clinic, a great many routine records were reviewed and it was decided that an eosinophil count of 4 per cent was the upper limit of normal. The pulmonary disease in this case was acute infection, not asthma. Perhaps some of the findings seen in the x-ray film are the result of periarteritis nodosa, I do not know. There is no way of establishing it or ruling it out, but it would explain all the symptoms.

Someone obviously thought of undulant fever as a possibility. One of my students just told me that he thought that that was the diagnosis in this case because all the symptoms that this patient had have been ascribed to undulant fever. Considering how often the brucellergen skin test is non-specifically positive, I would be unwilling to make the diagnosis in the face of a negative test. I doubt if all the things ascribed to undulant fever are due to it.

The most likely bet that I can make is that the patient had periarteritis nodosa. I am puzzled by the terminal bloody diarrhea, which suggests ulcerative colitis more than anything else, and also because of the fact that he had diarrhea at the onset of the illness. That is not usually a feature of periarteritis. I am at a loss to explain that. It is possible that he had ulcerative colitis as a terminal event, it sometimes happens. As I have said, beyond making the diagnosis of gallstones that show up by x-ray study, I have to speculate about the rest. Certainly he had a generalized constitutional disease that involved the kidneys, joints and gastrointestinal tract, and periarteritis nodosa would explain it.

DR WALTER S. BURRAGE: There are one or two points of interest not clearly brought out in the history. The patient had severe joint symptoms early in the game. He went to his place of occupation from his home on quite a number of occasions when he had to have crutches and be assisted in and out of the bus by the bus driver. The joint symptoms in the feet, ankles and knees were, there-

fore, more than of fleeting discomfort at such times.

One other point: the joint symptoms came earlier than the so-called pneumonia—that is, before he had been given sulfonamides.

In regard to Dr Beckman's question about the reason for taking the gastrointestinal series—it was ordered primarily because the patient had considerable nausea and vomiting, but also because we were trying to think of every possible lead. To our great surprise we found a local lesion. There was very little in the history to suggest this. When I saw him originally the possibility of some allergic manifestation was considered, such as angioneurotic edema. It soon seemed obvious, however, that an allergic mechanism was unlikely but that if present at all, it must have been of the delayed reaction type, which one thinks of in connection with periarteritis nodosa. There was little evidence for chronic arthritis. Periarteritis nodosa seemed the most likely diagnosis but one made with only modified enthusiasm.

DR JOHN W. CASS: During the past four or five years I saw him once in a while when his family physician was away. He asked me first to see him because he was acutely ill and had a temperature of 104°F. He complained bitterly of pain in the joints, although it was not possible to see anything abnormal about the joints. He could not move them without excruciating pain. This quieted down. He said it was like all the attacks except that there was no swelling. I asked him to call me if he had swelling again. Two years later he called and said that he had another attack with swelling. He had definite swelling of the hands, but more like urticaria than joint swelling. I did not see him again until he became very ill. I thought the patient had some type of atypical rheumatoid arthritis, and I referred him to Dr Burrage because the one time that I had seen him in an attack of joint pain and swelling I thought that it resembled angioneurotic edema. The urine was examined several times, and it was apparent from that time on that he had progressive signs of kidney disease. The albuminuria increased, there were more casts, and the amount of urine was definitely less. The terminal picture was one of wasting disease with definite signs of kidney disease. He definitely had atrophy of the muscles. There was no question about it. It may have been atrophy of disuse, but at the same time it was far out of proportion to what one would expect. I saw him within an hour of his death and did not realize that he was going to die so soon. I expected him to die in clear-cut uremia, but he was not drowsy. The only thing that I was clear about was that he had a terminal stage of some generalized disease. At first the picture seemed like rheumatoid arthritis, terminally, it was more in keeping with periarteritis nodosa.

CLINICAL DIAGNOSES

Fever of unknown etiology
 Periarthritis nodosa

DR BECKMAN'S DIAGNOSES

Periarthritis nodosa
 Gallstone

ANATOMICAL DIAGNOSES

Diffuse myeloma of the bone marrow
Amyloidosis of liver, spleen and kidneys
Superimposed Bence-Jones proteinuria, kidney?
 Gastric ulcer, healed
 Cholelithiasis
 Hemorrhagic enteritis
 Arteriosclerosis, generalized, moderate

PATHOLOGICAL DISCUSSION

DR MALLORY The autopsy on this man showed an enlarged liver and spleen and very greatly enlarged kidneys. The liver was very pale and firm and slightly waxy in character. The spleen presented visible granulations in the region of the corpuscles. The gross appearance was so characteristic of amyloid disease that an iodine reaction was done at the time of autopsy and was strongly positive. The gastric lesion appeared to be an old, partially healed, benign, peptic ulcer very close to the pylorus. At the time of autopsy we found nothing that would explain the existence of amyloidosis in this patient.

When the microscopical sections came through it was obvious that the majority of the bone marrow was replaced by immature cells only faintly resembling plasma cells but, nevertheless, within the limits of what we see in certain cases of multiple myeloma. Sometimes very severe amyloidosis does occur in association with myeloma, and I believe that is the histologic background in this case. The kidneys were very remarkable in that they showed only mild amyloid deposits but the most severe hyaline degeneration in the convoluted tubules that I have ever seen. There were also very numerous casts in some of the lower tubules. I did not pay much attention to them at first, but one of the pathologists, not knowing the history of the case, asked me if the man had a myeloma so there may also have been a Bence-Jones element in these kidneys as well as amyloidosis. The urine was never examined for Bence-Jones protein so that we are unable to determine that

CASE 35042

PRESENTATION OF CASE

A seventy-four-year-old egg tester was admitted to the hospital because of vomiting of four days' duration.

He had been well and working up until about three months before entry, when he suddenly

developed nausea, vomiting and generalized cramping pain. He also noted diarrhea, the stools being brown, liquid and not bloody. He was admitted to another hospital, where physical examination revealed a semicomatose man in acute abdominal pain. The skin was cold and clammy. The abdomen was slightly distended, tender and tympanic, and no peristaltic sounds were heard. The prostate was slightly enlarged. The blood pressure was 158 systolic, 70 diastolic. The temperature was 100°F (rectally). The urine had a specific gravity of 1.012 and gave a ++ test for albumin, and the sediment contained 0-2 white cells and 2-4 red cells per high-power field and + bacteria. The red-cell count was 3,970,000, with a hemoglobin of 11.7 gm, and the white-cell count 7750, with 63 per cent neutrophils. The blood sugar was 135 mg per 100 cc, the nonprotein nitrogen 136 mg per 100 cc, the carbon dioxide 32.5 milliequiv per liter and the amylase 64 units. A guaiac test of the stool was +++. A roentgenogram showed gas in the stomach and left colon. The kidneys were well outlined and normal in size, shape and position. The cecum and transverse and ascending colon were distended by gas, and barium flowed freely through the splenic flexure. The patient was unco-operative, and the examination was unsatisfactory. Three days later an upper gastrointestinal series revealed no abnormality in the esophagus, stomach or small bowel. A six-hour film showed the terminal ileum, cecum, transverse colon, descending colon and sigmoid partially outlined by barium. He was placed on Miller-Abbott tube for distention and given intravenous fluids, streptomycin and penicillin. Agglutination tests for typhoid O and H antigens, paratyphoid A and B and Proteus OX-19 were reported as negative. Stool culture showed no enteric pathogens. Repeated blood cultures were negative. After three days of therapy the nonprotein nitrogen was 162 mg, total protein 4.7 gm per 100 cc, phosphorus 5.5 mg per 100 cc and uric acid 11.8 mg per 100 cc. The diarrhea continued unabated. Intravenous fluids were continued but stopped on the twentieth hospital day. The temperature had fluctuated throughout the hospital stay between 99 and 101°F, rectally. The diarrhea began to come under control, and fluids were given more and more by mouth. The stool guaiac tests became negative, and on the eighteenth hospital day the nonprotein nitrogen had fallen to 32 mg per 100 cc and the carbon dioxide combining power had risen to 43 vol per cent. The urine specific gravity throughout the hospital stay remained fixed between 1.007 and 1.013. There had been continuous microscopical pyuria, the sediment averaging 15 to 25 white blood cells per high-power field. He remained very weak, and in view of what was considered to be the chronic nature of his disease, it was recommended that further care be continued in a chronic-disease hospital. He was

discharged to a convalescent home, where he remained two weeks.

In the interval, some seven weeks before admission to this hospital, the patient felt well with no specific complaints. Four days before entry he became confused and incontinent of urine. On the following day he began vomiting, became increasingly weak, and for forty-eight hours before admission had been unable to retain anything by mouth. The vomitus was occasionally "green bile" and never contained blood or coffee-grounds material. The bowels had moved regularly. There was some right abdominal and left chest pain.

Twenty-five years previously he was operated on for a "twisted bowel," which was "untwisted at the time of operation." For six years prior to admission he had noted episodes of diarrhea occurring every three or four months. For five years before admission he experienced urinary incontinence and nocturia. His normal weight had been 210 pounds, and a daughter stated that he had been losing weight progressively.

Physical examination revealed a somewhat disoriented, pale, dehydrated, elderly man in no acute distress. He regurgitated a green fluid regularly. The chest was clear, the diaphragm was high. There were dullness and decreased breath sounds and vocal fremitus at the right base, with egophony above. The heart was not enlarged to percussion. The abdomen was mildly distended and tympanic throughout. Peristalsis was decreased but of normal pitch. There was some tenderness on the left but no rebound tenderness. There were no rectal masses. The prostate was somewhat enlarged. The legs and sacrum showed a + edema.

The temperature was 98.6°F, the pulse 94, and the respirations 24. The blood pressure was 90 systolic, 60 diastolic.

The urine had a specific gravity of 1.012 and gave a + test for albumin, and the sediment contained 4-5 white blood cells and a rare red blood cell and hyaline cast per high-power field. The red-cell count was 3,500,000, with a hemoglobin of 13 gm, and the white-cell count was 15,100, with 94 per cent neutrophils. The blood nonprotein nitrogen was 48 mg and the total protein 4.8 gm per 100 cc, the chloride 102 milliequiv and the sodium 143.9 milliequiv per liter, and the blood sugar 104 mg per 100 cc. A stool gave a + guaiac reaction. On the following day the nonprotein nitrogen was

56 mg and the total protein 4.5 gm per 100 cc, the chloride 94 milliequiv, the carbon dioxide 28.1 milliequiv, the sodium 141.7 and the potassium 3.8 milliequiv per liter. A culture of the bladder washings grew abundant gram-negative cocci and colon bacilli.

In the hospital the patient was kept on intestinal suction and intravenous fluids. He became oliguric, the urine output being 100 cc in the first twenty-four hours after admission. He remained disoriented. A roentgenogram of the abdomen on the day of admission showed the Harris tube in the stomach. The colon was filled with gas and fecal material but was not definitely dilated. Gas and fecal material were present in the rectum. There were dilated, air-filled loops of small bowel. A roentgenogram of the chest showed homogeneous ground-glass density on the right and patches of increased density on the left. On the second hospital day the white-cell count rose to 25,000, with 98 per cent neutrophils. The urine contained many white blood cells. The temperature was 99°F. On the third hospital day his outward appearance was about the same. He was still confused. The abdomen appeared to be a little more distended. Peristalsis was absent. There was more resistance and tenderness in the lower quadrants. The temperature rose as high as 100°F, and the pulse and respirations remained at 120 and 24, respectively. The urine output was negligible. The white-cell count was 22,500, with 98 per cent neutrophils. Twenty-four hours later the temperature was 99.4°F, the pulse 115, and the respirations as high as 28. The blood pressure was 70 systolic, 40 diastolic. The urine output during the previous day had been less than 50 cc. The nonprotein nitrogen was 90 mg per 100 cc, and the chloride 93 and the carbon dioxide 25 milliequiv per liter. On the following day the patient was semicomatose, with a uremic odor. On the following morning he died.

DIFFERENTIAL DIAGNOSIS

DR DANIEL S. ELLIS: It seems to me that the object of this case is primarily to state whether or not this patient had some intra-abdominal disease in addition to renal disease, which is quite apparent. At the time of the first admission because of abdominal pain, nausea and vomiting he was found to have definite evidence of renal disease and uremia, and in the subsequent course of events he was treated with antibiotics and paren-

teral fluids. The gastrointestinal symptoms disappeared, the urinary function returned to approximately normal and he was discharged. It is unfortunate that this admission was at another hospital because we do not have the x-ray films. Therefore, we have to take at face value the statement that no gastrointestinal-tract disease was demonstrated by the various barium examinations done at the time of this illness.

There are several things that make me wonder a little as far as the abdominal pain, nausea and vomiting and diarrhea are concerned. In the absence of any demonstrated abnormal signs, either on physical examination or x-ray examination of gastrointestinal tract or abdomen, I am forced to believe that the gastrointestinal symptoms were on the basis of uremia. It is well known that patients with uremia may have abdominal pain, diarrhea and an ulcerative process involving the entire gastrointestinal tract. The only thing that makes me hesitate a little bit is the amylase report of 64 units. This is high in our laboratory. This is only one report, and I think that I will merely mention it as being abnormal. This man could have had pancreatitis. The low white-cell count is a little bit against it. The fact that examination later showed a leukocytosis makes me think that if he had had a real pancreatitis or intra-abdominal infection at the time of the first admission, it would have been evidenced by an elevation of the white-cell count, which was not observed. I believe that he was uremic, that he was moderately acidotic, and that he was having diarrhea and bloody stools on the basis of renal disease. This theory is further supported by the fact that when treated with supportive measures tending to rehydration to stimulation of urinary output and to control of infection, he improved, and his abdominal symptoms subsided. At the time of discharge he was not having diarrhea, pain, nausea or vomiting, the nonprotein nitrogen was normal but he still had white cells in the urine.

The second episode of illness, as much as I have studied it and tried to arrive at a decision, I am unable to make anything more of than an exacerbation of renal disease in an elderly man, with renewed renal failure and uremia. This time he did not have as much diarrhea. He did have a markedly increased leukocytosis and at this time had a positive urine culture. I would like, if

possible, Dr Wyman, to see any films that you may have to be sure again that some trouble in the abdomen was not developing and to make sure that he did not have pneumonia.

DR STANLEY M. WYMAN: These portable films taken on a very sick patient are of poor quality. They show hazy, homogeneous density in the right chest laterally, which obscures the right leaf of the diaphragm and appears quite consistent with fluid. The right lung shows, as far as I can see, no definite intrinsic disease, and I am unable to see any active process going on in the left lung. The film of the abdomen shows, as reported, gas in nondilated loops of large and small bowel down to the rectum. I do not see any unusual masses or any abnormal calcification except in the prostate.

DR ELLIS: Would you say there was any difference between the distention in the large or the small bowel? Is there any point of obstruction that you can see?

DR WYMAN: No, I cannot make a diagnosis of either large-bowel or small-bowel obstruction.

DR ELLIS: This patient is said to have been operated on once for volvulus of the intestinal tract. It is reported that this was untwisted at the time. At the present admission he had nausea and vomiting, the vomitus containing bile, so that he was regurgitating small-bowel contents. Certainly I could not exclude the possibility that he had an intestinal obstruction. On the other hand, I do not believe this to be true. I believe that the distention seen in the x-ray film is that of a critically ill, elderly man, and the gas-filled loops are probably those of ileus and loss of tone rather than obstruction. The vomiting also I think, goes with the renal disease. I am going to say that all the symptoms are on the basis of renal disease.

The problem is, What kind of renal disease or urinary-tract disease did this man have? I cannot get away from the definite evidence of an infection, which was manifested by the large number of white cells, positive urine culture and a white-cell count going as high as 22,500. So I believe that we are probably dealing with chronic pyelonephritis rather than a chronic glomerulonephritis. The fall in blood pressure throughout the illness, I think, was probably not due to any acute coronary insufficiency but to a debilitating illness, gradually progressing, in an acutely toxic, critically ill man, who probably had some pneumonia and atelectasis, but I do not

believe we can say that he had lobar pneumonia. The fluid in the chest and the pitting edema can be explained by a combination of things—for example, the low serum protein, uremia and renal disease.

My final diagnosis, without “hemming and hawing” any more, is that the patient had chronic pyelonephritis with uremia. He had some terminal atelectasis or bronchopneumonia and a right hydrothorax, and I have insufficient evidence to go any farther. I do not believe that he had any intra-abdominal disease. As already mentioned from the record there is a possibility of pancreatitis and possibly he had had volvulus of the small bowel with obstruction to account for the nausea and vomiting, but I would question that. I cannot make a diagnosis of intra-abdominal disease on the history as given.

DR DONALD S. KING: I had an advantage over Dr. Ellis because I saw this patient while he was alive and I had a chance to examine his abdomen. In fact, the day before he died I sat down with his problem and put my conclusion in the record. However, I did not do well. We were confused at first because he seemed to be having exactly the same symptoms when we saw him as he had had in the other hospital. He was discharged from that hospital with a diagnosis of uremic gastroenteritis, and he seemed to get along perfectly well on that diagnosis until he was admitted to our wards. Our first impression was that he again had uremia with gastroenteritis, and this diagnosis was sustained in part by the oliguria. But when we found that his nonprotein nitrogen was around 50 mg per 100 cc, we began to doubt whether uremia would explain all the findings. We were particularly disturbed when his white-cell count began to rise. But I never realized how serious his abdominal condition was, and I thought that he might have a mesenteric thrombosis.

DR ELLIS: There is no detailed report of the examination of the abdomen, which might be fairly important. It just says that there was resistance and tenderness in the lower quadrant. Did he have real spasm and tenderness? If so, was it in the region of the bladder and the lower ureter?

DR KING: There was no marked tenderness or spasm that I can recall. Is Dr. Littlefield here? He knows more about that.

DR JOHN W. LITTLEFIELD: I agree to that. The initial surgical examination will describe it, I think.

DR KING: The record states that on examination the patient was pale, slightly disoriented and acutely ill. The abdomen was full and soft, and then the record says “tender”—but does not state where—without masses and with absent peristalsis. At that time the surgeon thought that uremia would be a satisfactory diagnosis.

DR ELLIS: Was the patient ever sigmoidoscoped?

DR KING: I think he was not. He was a very sick man.

DR ELLIS: It is obvious that he had an ulcerative process going on in the intestinal tract. I think that there are any number of possibilities if he did not have what I have previously said. I think he had. But on the basis of the record I have to leave it there.

DR TRACY B. MALLORY: I would like to ask if the clinicians remember any patient with uremic enteritis who recovered from the episode.

DR MARIAN ROPES: I cannot remember having seen it.

DR MALLORY: It is a fairly common condition immediately before death, and I do not know whether the patient ever recovers from it or not.

DR KING: The discharge diagnoses from the other hospital were chronic nephritis, uremia, uremic gastroenteritis and benign prostatic hypertrophy.

DR ELLIS: I should like to ask Dr. Ropes if the uric acid of 11.8 mg per 100 cc is of any significance.

DR ROPES: At the time he had evidence of so much retention that I think it means nothing.

CLINICAL DIAGNOSES

Chronic nephritis, with uremia
Intestinal obstruction of undetermined cause.

DR ELLIS'S DIAGNOSES

Chronic pyelonephritis
Chronic glomerulonephritis?
Uremia
Right hydrothorax
Bronchial pneumonia—atelectasis
Generalized arteriosclerosis
Benign prostatic hypertrophy

ANATOMICAL DIAGNOSES

Carcinoma of colon, with probable perforation
Generalized peritonitis
Nephrosclerosis
 Cholecystitis and cholelithiasis
 Anasarca
 Benign prostatic hypertrophy
 Operative wound, old posterior gastroenterostomy

PATHOLOGICAL DISCUSSION

DR MALLORY The autopsy on this patient, I am sure, was a complete surprise to everyone. The major lesion was a cancer of the bowel located at the splenic flexure. This was about 4 cm long, completely encircling the bowel, which was very deeply ulcerated. There was a generalized fibrino-purulent peritonitis of sufficient age so that it had become separated into a great many pus-filled cavities, separated from one another by fibrinous adhesions. Actual perforation of the bowel could not be demonstrated with a probe at the time of autopsy, but since one of the larger intra-abdominal abscesses was in the immediate neighborhood of the lesion, I have no doubt that it had perforated and was the source of the peritonitis.

The lungs showed very marked congestion, atelectasis and edema but no pneumonia. There was pleural effusion of 900 cc on the right side. The kidneys weighed just over 300 gm, had a slightly narrowed cortex and microscopically showed a severe degree of arteriolar narrowing and hyalinization—the type of kidney one would expect to see with a benign hypertension. The process did not look far enough advanced to have in itself been the cause of the uremia, although to try and guess

from the appearance of such a kidney whether or not the patient had uremia is very dangerous, of course.

The former operation, described only as an operation for twisted bowel, had been a gastroenterostomy. We found nothing to explain why that had been done. The gastroenterostomy was patent. Our opinion was that the patient had a moderate grade of vascular nephritis, which probably alone would not have produced uremia but did so in association with peritonitis, and the dehydration that would go with that. A considerable degree of nitrogen retention is a common phenomenon in general peritonitis.

DR ELLIS Did he have the peritonitis when he was admitted to the first hospital?

DR MALLORY I cannot say whether or not he had some degree of peritonitis in the upper abdomen the first time. He had some old, fibrous adhesions, which were most extensive in the region of the previous operative scar. I do not believe I can say whether some of them were produced by an attack of localized peritonitis weeks before at the time of the first illness. They may have traced way back to the original disease twenty-five years previously.

DR ELLIS It is quite possible that peritonitis was at first controlled by the streptomycin and penicillin. After these were stopped it flared up again in more chronic, localized form. It certainly is true that we often see kidneys that are borderline and then tipped into failure by any acute process. I think it possible in view of the findings to explain the uremia on that basis. It seems strange that the peritonitis was not more manifest clinically.

DR KING We thought so too.

DR MALLORY The paralytic ileus was the only evidence positively in favor of it.

BUDGET FOR 1949

As THE country enters into that period of the year immediately following the winter solstice when it wrestles, individually and collectively, with its fiscal problems, some thought must also be given to the pecuniary affairs of the Massachusetts Medical Society. These affairs, as the Treasurer will bear witness, have grown, shortly the Council will vote upon the largest budget in the history of the Society.

None of the items in this budget need cause concern, for the Society is solidly solvent, all of them require the scrutiny of the councilors, who should have a clear conception of the magnitude of the works that they are directing and their importance.

The largest single item in this budget is the \$27,000 that goes to the support of the Boston Medical Library, and represents one of the important reasons for the increase in the Society's membership assessment in 1948. For the five dollars of his assessment that is so allocated, each fellow of the Society receives membership in the Library and, perhaps more important, the consciousness that he is contributing a modest share toward the support of a basic factor in medical education and in intellectual improvement in his profession. This support must be reaffirmed so long as it is needed, as one of the soberest and most mature commitments that a physician can make.

Other items in the Society's budget are concrete evidence of the fact that the relation of physicians to the public have changed, that they have become more complex and that they are subject to pressures that call for constant strengthening from within. The payroll has justifiably increased as headquarters duties have become more numerous and more exacting. The expenses of the officers and committees in discharging their functions have increased, a considerable share of this increase being charged to public relations, including the expenses of the Committee on Legislation, the refund to the district societies was increased last year from \$4000 to \$8000, the employees' pension plan adds \$4000 yearly, the Council has voted \$10,000 annually to the Medical Benevolent Society.

The sum of \$10,000 has again been allocated to the *Journal* as the only commitment that the Society is presently asked to make for over 6000 subscriptions and the publication of the Proceedings, in four years \$5000 only of this appropriation has been retained for the use of the *Journal*.

The budget requested for 1949 is \$142,155, the income of the Society being probably over \$150,000. The margin is safe, but it must in the future as at present be carefully guarded.

SWORDS AND PLOUGHSHARES

How can health and medical-care standards of American soldiers and airmen be kept at their present level, the highest of any army in the world today? The Army Advisory Committee* asks the

*To save — not to destroy. *Ball Army Advisory Committee* 2 1, October 1948.

question, one answer to which may be found in the Medical Department's plan for peace-time operation of Reserve Officers Training Corps units in the approved medical schools of the United States. An account of the work of these units within the framework of the undergraduate medical curriculum is given elsewhere in this issue of the *Journal*. To those whose recollections of medical ROTC are strongly colored by past experience of litter bearing and close-order drill, unmistakable signs of progress will be revealed.

ROTC units now installed are designed to obtain a total enrollment of 8000 for all four classes in medical schools, and to produce annually about 2000 first lieutenants. In the year 1946-1947, 20 units were in operation, in 1947-1948, 23 units were added, and in 1948-1949 there are an additional 6, bringing to 49 the total units now operating. Within a period of three years this has therefore become a universal feature of medical education in the United States. On a similar elective basis the Army has established 18 units in the dental schools, 6 in the veterinary schools, and 4 in the schools of pharmacy.

The purpose of the medical ROTC is to develop a body of Reserve Medical Corps officers who will be capable of performing professional duties and also of taking care of themselves within the structure of the Army, and without further training on mobilization day—or at any time when they may be called to active service. A secondary mission of the plan is that of acquainting the medical student with the facts concerning a career in the Army Medical Department, with the further possibility that he will become interested in obtaining an Army internship and in applying for a regular commission.

All this is preparedness in the best sense—preparedness to save—not to destroy, to conserve—not to dissipate. It is preventive medicine, organized on a scale and basis heretofore unknown.

A MEETING OF MINDS

PHYSICIANS are making up their minds about the future of the broad field of psychiatry, as evidenced by the International Congress on Mental Health, held in London in August, 1948. Two thousand men and women, representing fifty-five

countries, at that time discussed mental health and formulated specific plans for its betterment throughout the world. Although the largest number of participants were psychiatrists, the preliminary study groups were made up not only of physicians but also of psychologists, sociologists, anthropologists, educators, theologians and representatives of relevant disciplines.

The purpose of the Congress was threefold: to bring together psychiatrists from all the world, that they might secure an over-all picture of the psychiatric needs of human beings and formulate methods of solving these problems, to study the psychologic causes of war and the part physicians may play in prevention, and to form an international organization to engage actively in promoting mental health in every nation.

Representatives from fifty-five countries participated in the incorporation of this organization, with offices in Geneva. Membership is made up of professional societies in the related disciplines concerned with mental health as well as of the mental-hygiene societies in each participating country. These member associations will send representatives to the annual meeting of the Mental Health Assembly. It is expected that the work of the World Federation for Mental Health will be incorporated with the World Health Organization and the whole correlated with the United Nations Organization, the World Federation offering a means for transnational collaboration on the problems of mental health.

There can be no question that this is a most important development in the field of medicine and one in which physicians will be interested and in which they will want to participate, for mental illness is probably the greatest single cause of suffering throughout the world, and it is to physicians that people must turn for individual treatment, guidance and public-health measures directed toward its prevention. For the first time in history these facts are now generally recognized, and the organization that has been perfected deserves support. To this end physicians are increasing their knowledge of the physiologic, psychologic and sociologic factors relating to mental health, that they may be better prepared to treat patients, formulate mental-

hygiene principles and implement measures for the improvement of mental health

Plans have been completed for the President of the United States to proclaim a Mental Health Week in April, 1949. This will be followed by proclamations from the governors of the forty-eight states and wide publicity through press and radio. There will be active co-operation from medical societies and other organizations directed toward the betterment of mental-health conditions in this country. In all this the medical profession will assume the leadership that it has always shown in matters pertaining to individual and public health.

PIED PIPERS OF MADISON

CURRENT researches in the department of zoology of the University of Wisconsin on the habits of rodents are beginning to reveal interesting facts concerning the life and manners of these small inhabitants of the underworld. As a result it is believed that a careful study of the life habits and population cycles of rats, bats, mice and muskrats may lead to improved methods of rodent control.

Five College of Agriculture animal buildings, infested with wild mice, comprise the location of the study, here eager scientists, employing the reverse process of belling the cat, are catching and marking the diminutive enemies of the new look.

A number of facts have already been elicited. Mice, when living in peace and comfort, rarely range more than 30 or 40 feet from home, and rats seldom farther than 100 feet from the food supply. Since the rate of reproduction averages 30 young per year per female with about 5 survivors, overpopulation soon becomes a factor, however, with competition and outbreaks of civil war resulting, as with human beings. Perhaps from this analogy the frequently quoted question may arise "Are we men or are we mice?"

Various methods of rodent control have been tested and evaluated. The best of these is prevention, and to discourage the rodent population this implies cutting off the food supply. Entry holes must be plugged, garbage removed, refuges cleaned and cupboards either mouseproofed or kept as bare as

Mother Hubbard's. Rats abandoning their native locality for any reason are never welcomed into another colony.

In the frontal attack poisoning is the least effective weapon, a good hunting cat one of the best. The old-fashioned snap-trap remains a steadily effective mouse-eliminator. Not mentioned as participating in the Wisconsin field trials is a new and remarkable gadget for the mass liquidation of domestic rodents. This machine, equipped with an electric eye, is set up adjacent to a rat runway. When a victim crosses the beam he is quietly seized by the neck, electrocuted and tossed aside, after which this supreme effort of the electrocutioner's art promptly resets itself.

The rodent population so far is nearly holding its own, but to do so it must live dangerously.

Fourth-year students in approved medical schools are reminded of the *Journal's* prize essay competition on preventive medicine. For further information see *The New England Journal of Medicine*, September 30, 1948, p 525, or write to the editor.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

ABBE — Alanson J. Abbe, M.D., formerly of Fall River, died on January 3. He was in his eighty-eighth year.

Dr. Abbe received his degree from Harvard Medical School in 1885. He was formerly secretary-treasurer of Bristol South District Medical Society and ophthalmic surgeon at Umon Hospital, Fall River.

A son, a daughter and two grandchildren survive.

CHENERY — William E. Chenery, M.D., of Brookline, died on January 3. He was in his eighty-fifth year.

Dr. Chenery received his degree from Harvard Medical School in 1890. He was formerly surgeon at St. Elizabeth's Hospital, consultant at Boston Dispensary, New England Deaconess and Evangeline Booth hospitals and a member of the staff of New England Baptist Hospital. He was a member of the American Academy of Ophthalmology and Oto-Laryngology, American Laryngological and Rhinological and Otological Society and a fellow of the American College of Surgeons and American Medical Association.

His widow and a niece survive.

GOLDBERG — Samuel B. Goldoerg, M.D., of Medford, died on January 5. He was in his forty-sixth year.

Dr. Goldberg received his degree from Middlesex University School of Medicine in 1928.

His widow, a son, a daughter, three brothers and a sister survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATH

STICKNEY — Henry L. Stickney, M.D., formerly of Manchester, died on December 17. He was in his seventy-eighth year.

Dr. Stickney received his degree from University of Vermont College of Medicine in 1894. He had served in various Veterans Administration hospitals and at one time owned and operated the Hillcrest Hospital in Manchester. He was formerly a member of the staff of the Mayo Clinic, Rochester, Minnesota, and was a fellow of the American Medical Association.

His widow, two sons, a daughter, a brother, eight grandchildren and a great-grandchild survive.

*Four year median

†Six-year median

COMMENT

Diseases above the seven-year median were chicken pox, diphtheria, German measles and mumps.

Diseases below the seven-year median were bacillary dysentery, lobar pneumonia, poliomyelitis, scarlet fever, typhoid fever, undulant fever and whooping cough.

Diphtheria was still too prevalent. For ten consecutive years, 1936-1946, the incidence was lower than that during December. A total of 139 cases was reported during the last four months of 1948, compared to 85 cases in the same period in 1947.

The incidence of chicken pox was the highest ever reported for December, and that for measles was the highest since 1925. The frequency of mumps, which was still higher than the seven-year median, seems to be declining.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Diphtheria was reported from Arlington, 3, Blackstone, 1, Boston, 23, Bridgewater, 1, Brookline, 1, Chelsea, 2, Danvers, 2, Everett, 2, Haverhill, 1, Lowell, 1, Nahant, 4, Revere, 1, Salem, 1, Somerville, 1, Springfield, 1, Waltham, 1, Winchester, 1, total, 47.

Dysentery, amebic, was reported from Boston, 1, total, 1. Dysentery, bacillary, was reported from Boston, 1, Worcester, 1, total, 2.

Encephalitis, infectious, was reported from Andover, 1, Malden, 1, Westfield, 1, Worcester, 1, total, 4.

Lymphocytic choriomeningitis was reported from Winthrop, 1, total, 1.

Meningitis, meningococcal, was reported from Boston, 1, Haverhill, 1, New Bedford, 1, Pittsfield, 1, Somerville, 2, Williamstown, 1, Winthrop, 1, total, 8.

Meningitis, Pfeiffer-bacillus, was reported from Malden, 1, Southbridge, 1, Springfield, 3, total, 5.

Meningitis, pneumococcal, was reported from Braintree, 1, Chesterfield, 1, Gloucester, 1, Medford, 1, Somerville, 1, West Springfield, 1, Weston, 1, total, 7.

Meningitis, staphylococcal, was reported from Chicopee, 1, total, 1.

Meningitis, undetermined, was reported from Adams, 1, Avon, 1, East Brookfield, 1, Milton, 1, West Boylston, 1, Worcester, 1, total, 6.

Poliomyelitis was reported from Hardwick, 1, West Springfield, 1, total, 2.

Salmonellosis was reported from Boston, 2, Lynn, 1, Winchester, 1, total, 4.

Septic sore throat was reported from Boston, 4, Medford, 2, total, 6.

Tetanus was reported from Lawrence, 1, total, 1.

Trichinosis was reported from Boston, 1, total, 1.

Tularemia was reported from Sandwich, 1, total, 1.

Typhoid fever was reported from Boston, 1, Swansea, 1, total, 2.

Undulant fever was reported from Grafton, 1, total, 1.

CONSULTATION CLINICS FOR CRIPPLED
CHILDREN IN MASSACHUSETTS

The December schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

CLINIC	DATE	CLINIC CONSULTANT
Haverhill	February 2	William T. Green
Lowell	February 4	Albert H. Brewster
Salem	February 7	Paul W. Hugenberger
Gardner	February 8	Carter R. Rowe
Brockton	February 10	George W. Van Gorder
Worcester	February 11	John W. O'Meara
Greenfield	February 14	Charles L. Sturdevant
Springfield	February 15	Garry deN. Hough, Jr.
Pittsfield	February 16	Frank A. Slowick
Hyannis	February 24	Paul L. Norton
Fall River	February 28	David S. Grace

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

MISCELLANY

PRESIDENT OF THE AMERICAN ACADEMY
OF PEDIATRICS

Dr. Warren R. Sisson, of Boston, having served for a year as president-elect of the American Academy of Pediatrics, has assumed the office of president. Dr. Sisson, a graduate of Johns Hopkins University School of Medicine and formerly a member of the Department of Pediatrics of Harvard Medical School, served also as chairman of the committee for the Study of Child Health Service of the Academy.

CORRESPONDENCE

STATISTICS OF PNEUMONIA

To the Editor: The editorial "Influenza and Pneumonia" in the December 9 issue of the *Journal* is timely and appropriate, but by implication it perpetuates an error when it states "A most significant downward trend in the figures began in the early 1930's, when specific serum treatment for many types of pneumonia was introduced." The figures for Massachusetts, where an intensive serum program was conducted in the 1930's, do not show any downward trend in that decade until 1938, after the use of chemotherapy became widespread. As a matter of fact the Massachusetts figure for 1936 (96.3) is higher than that for 1930 (95.0), and back in 1927 it had dipped to 97.5.

All that we are ever likely to know about the serum treatment of pneumonia is now recorded. It is too hard to let these legends continue, as a profession we do not need to be flattered and do not wish to be falsely recorded by such implications in the history of medicine. I am convinced that a careful study of pneumonia between 1920 and 1937 will fail to reveal any one circumstance that satisfactorily explains the reduction of mortality, it is extremely doubtful that our bedside practices had anything to do with it. Personally, I was never convinced that the serums we used in the 1930's were any more effective than those available for the more common types in 1920. Certainly, we have no evidence that any of them compare with the chemical and biologic agents of the past decade.

DWIGHT O'HARA, M D

Waltham, Massachusetts

NOTE A previous editorial, entitled "Pneumococcal Pneumonia," which appeared in the April 17, 1947, issue of the *Journal*, had already taken cognizance of the facts that Dr O'Hara's letter re-emphasizes. The reference to the figures quoted in the recent editorial was for industrial policyholders from the country as a whole as compiled by the statisticians of the Metropolitan Life Insurance Company. In these figures the temporal if not the causal relation of the drop in pneumonia mortality to the use of serums was implied. The beneficial effects of antipneumococcal serums, particularly those prepared in rabbits and available just prior to the introduction of effective sulfonamides, now constitute only a matter of historical interest. It should be pointed out, however, that much firmer convictions are held by most of those with considerable and intimate experience with the use of serums in large numbers of cases. Regarding the effects on the mortality statistics for Massachusetts, too many factors are involved in the compilations of such figures to warrant any serious interpretations, controversies or comparisons with carefully studied clinical material compiled by competent observers. — Ed

A CORRECTION

To the Editor I appreciate very much the honor of the editorial comment in the December 9 issue of the *Journal*. I would, however, like to make two minor corrections and add a note.

My college class was 1908, 1911 for my medical class was correct.

The decoration of the Order of the White Lion was given in 1946 to all the members of the American Medical Mission to Czechoslovakia under the auspices of the Unitarian Service Committee in acknowledgment of the helpful work in restoring the medical friendship and co-operation of the two countries. Among those in Boston receiving the decoration were Drs Joseph Aub, Otto Krayer, Joseph Volker and Joseph Lazansky. At the time of my visit to Prague in April, 1948, I was on my way to another American Medical Mission of the Unitarian Service Committee, this time to Greece and Italy, in which I was associated with ten other doctors, including several more from Boston — namely Drs Chester Jones, Reidar Sognnaes and Herman DeWilde. I spent a few days in Prague (en route to Athens) to attend the six hundredth anniversary of Charles University, the oldest university in Central Europe, in acknowledgment of the past accomplishments of that great institution. Professor René Leriche, of France, and I received honorary doctorates from the faculty of medicine. Other medical candidates were not present, but honorary degrees were bestowed by other faculties on other foreign guests.

In my new role as adviser of the National Heart Institute and executive director of the National Advisory Heart Council I shall continue to reside in New England and to practice medicine half time, following patients whom I have seen in the past. Adjoining my own private office at 264 Beacon Street is a branch office of the National Heart Institute, one of the National Institutes of Health under the United States Public Health Service whose headquarters are at Bethesda, Maryland.

Boston, Massachusetts

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Practice of Allergy. By Warren T Vaughan, M D. Revised by J Harvey Black, M D. 4th, cloth, 1132 pp, with 333 illustrations and 81 tables. Second edition. Saint Louis: The C V Mosby Company, 1948. \$15.00.

This treatise, first published in 1939 by Dr Vaughan, has been revised for the second edition by Dr Black, who assumed the authorship after the death of Dr Vaughan. The text has been revised to bring the subject up to date. The chapters on fungous infection with associated allergy and on vital capacity have been rewritten. A large bibliography follows the text, and a comprehensive index concludes the volume. The type and printing are excellent, but the use of a coated paper makes the volume very heavy. This encyclopedic treatise is recommended for all medical libraries and to all specialists in its field.

Pioneer Life in Kentucky, 1785-1800. By Daniel Drake, M D. Edited from the original manuscript, with introductory comments and a biographical sketch by Emmet F Horne, M D. 8th, cloth, 257 pp, with 8 illustrations and frontispiece. New York: Henry Schuman, 1948. \$4.00.

The letters of Dr Daniel Drake, edited by his son, Charles Daniel Drake, were first published in 1870. The letters were republished in 1907, and both editions have long been out of print. In an examination and comparison of the original letters, now in the library of the Cincinnati General Hospital, with the published letters, Dr Horne found many discrepancies and omissions. It was found that Dr Charles Drake took many liberties with his father's letters in an attempt to improve their literary style. In this edition the letters have been faithfully reproduced in Dr Drake's phraseology from the original manuscript letters. Dr Daniel Drake was a pioneer western physician, the first medical student of Cincinnati and a professor at Transylvania University at Lexington, Kentucky, in 1817. He was prominent in Ohio affairs, establishing the Medical College of Ohio, the Western Museum, the Cincinnati College and the *Western Journal of the Medical and Physical Sciences*, of which periodical he was editor from 1827 to 1838. This important book should be in all medical and general historical collections.

Treatment of Heart Disease. By William A. Abrams, M S, M D, Ph D. Associate professor of medicine, Northwestern University Medical School and attending physician, Michael Reese Hospital, Chicago. 8th, cloth, 195 pp, with 11 illustrations. Philadelphia: W B Saunders Company, 1948. \$3.50.

This monograph has been written for the general practitioner and medical student as a systematic and practical guide in the treatment of heart disease. It reflects the experience of the author gained in teaching and in private practice and consultation work and does not include methods of treatment used by other heart specialists. The material offered is confined to therapy and does not discuss etiology, symptomatology and diagnosis. A comparatively large amount of space is devoted to congestive heart failure because the author believes that the majority of persons with almost any form of organic heart disease ultimately develop this condition. The first chapter discusses the pharmacologic action of drugs used in treatment, followed by chapters on the various heart diseases. The text is well printed with a good type. The use of a coated paper is not justified by the number of illustrations. A long bibliography concludes the text and there is a good index.

A History of the Heart and the Circulation. By Frederick A. Willius, M D, M S in Med, senior consultant in cardiology, Mayo Clinic, professor of medicine Mayo Foundation for Medical Education and Research Graduate School, University of Minnesota and Thomas J. Dry, M A, M B, Ch B, M S in Med, consultant, section on cardiology, Mayo

Clinic, associate professor of medicine, Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota 8°, cloth, 456 pp., with 170 illustrations Philadelphia W B Saunders Company, 1948 \$8 00

This new history of the heart and circulation is divided into three parts. The first presents a chronologic history from 5000 B C to 1925 A D, arranged by periods. The second consists of twenty special biographies of pioneers in various aspects of the subject, from Hippocrates (c 460-c 377 B C), to Sir Thomas Lewis (1881-1945). The third is a chronologic presentation according to subjects. To each chapter there is appended an extensive bibliography. Two good indexes of authors and subjects conclude the volume. The text is well written in a seminarrative style and is illustrated with portraits of physicians discussed in the text. The chronologic tables in the third part should prove very valuable for reference purposes. The book should be in all medical-history collections and in all medical libraries, both small and large.

Diagnostic Procedures for Virus and Rickettsial Diseases Published by The American Public Health Association 8°, cloth, 352 pp., with 20 illustrations New York American Public Health Association, 1948 \$4 00

This book is the joint work of the members of a special committee of the American Public Health Association. Seventeen diseases are discussed by authorities on the various diseases. Laboratory methods applicable to the various diseases are described in the chapters dealing with the diseases. A good index concludes the volume, which is well published. It should be in all medical libraries and medical laboratories.

The Salicylates A critical bibliographic review By Martin Gross, M D, research assistant (assistant professor), Laboratory of Applied Physiology, Yale University School of Medicine, and Leon A Greenberg, Ph D, associate professor in applied physiology, Yale University School of Medicine. With an introduction by Howard W Haggard, M D, director, Laboratory of Applied Physiology, Yale University School of Medicine 8°, cloth, 380 pp., with 20 illustrations and 29 tables New Haven Hillhouse Press, 1948 \$6 00

This monograph is one of a series projected by the Institute for the Study of Analgesic and Sedative Drugs. The volume on acetanilid was published in 1946. The literature reviewed 4093 titles, and the bibliography uses 173 pages of the book. The first part of the work analyzes and reviews the chemistry, physiology, pharmacology, toxicology and therapeutic uses of the salicylates. The text is well printed with a good type on light paper. An index of subjects concludes the volume. The book is recommended as a reference source for all medical libraries.

The Frightened Child By Dana Lvon 8°, cloth, 186 pp New York Harper and Brothers, 1948 \$2 50

This novel with a psychologic trend has a physician as one of its characters.

Your Skin and Its Care By Howard T Behrman, M D, and Oscar L Levin, M D 12°, cloth, 255 pp., with 11 illustrations New York Emerson Books, Incorporated, 1948 \$2 50

This manual is written for the laity and is devoted to the hygiene of the skin in health and disease, with chapters on the hair, sebaceous glands and quackery in relation to dermatology. The material is well arranged, and the text well written in a simple manner. A glossary of terms concludes the text. There is a good index. The volume is a good example of a popular medical manual.

NOTICES

ANNOUNCEMENT

Dr Robert R Commons announces the opening of his office for the practice of internal medicine at 121 North San Vincente Boulevard, Beverly Hills, California.

NEW ENGLAND HEART ASSOCIATION

A meeting of the New England Heart Association will be held in the Auditorium, Boston University School of Medicine, 80 East Concord Street, on Monday, February 14, at 8 15 p m, Dr Robert W Wilkins presiding.

PROGRAM

Observations on Normal and Pathologic Physiology of Postarteriolar Vascular Beds in the Human Forearm and Calf Drs J Litter and R W Wilkins
The Relative Velocity of Plasma and Cells in the Circulation of Man Drs C P Emerson, E D Freis and J R Stanton
Prognosis for Surgically Treated Hypertensive Patients. Dr P H Smithwick
Comparative Hemodynamic Effects of Small Intravenous Doses of Epinephrine in Normotensive Subjects and in Hypertensive Patients before and after Sympathectomy Drs W E Judson, C M Tinsley and J W Culbertson.
A Case of Pheochromocytoma Extensively Studied before and after Surgical Removal Drs R W Wilkins, W E Greer, J W Culbertson, C H Burnett, M H Halpern, J Litter and R H Smithwick.

Interested physicians and medical students are cordially invited to attend.

MASSACHUSETTS MEDICO-LEGAL SOCIETY

The winter meeting of the Massachusetts Medico-Legal Society will be held in the Department of Legal Medicine, Building E-1, Harvard Medical School, on Wednesday, February 9, at 2 30 p m.

PROGRAM

When to Accept Jurisdiction Dr Richard Ford
The Medical Examiner's View Dr Timothy Leary
Unusual Medicolegal Problems Dr Alan R Montz
Establishment of identity and time, cause and manner of death of unknown person twelve years after death.
The benefits of a second autopsy after three years in a wet grave

HELEN PUTNAM FELLOWSHIP

The Helen Putnam fellowship for advanced research in genetics or mental health, open to women scholars who have their doctorate or who possess equivalent qualifications, will be offered by Radcliffe College for the academic year 1949-1950. The award carries a stipend of \$2600 a year with the possibility of renewal.

Applicants are asked to submit a plan of research, and preference will be given to those whose research is already in progress.

Applications should be returned to the Secretary of the Graduate School, Radcliffe College, not later than April 1.

FURTHER EXPERIENCES WITH INJURED BILE DUCTS*

A New Method of Repair

FRANK H. LAHEY, M.D.†

BOSTON

EARLY in my surgical experience I became interested in the problem of injuries to the bile ducts and in 1923 wrote my first paper^{1, 2} on this subject, dealing with the results obtained by transplanting completely external fistulas when common and hepatic ducts had been so injured and severed that all or practically all the bile was discharged ex-

ternally. Since that time we in the clinic have had a continuing interest in the problem of the management of the patients with strictures of the common duct and defects in the common and hepatic ducts from excising sections of them.

We have operated upon 227 patients for benign strictures of the bile ducts. There have been 27

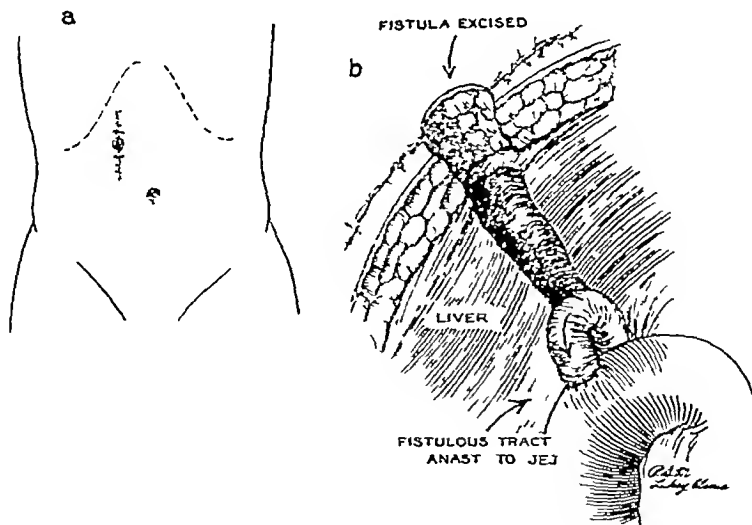

FIGURE 1 Transplantation of Completely External Fistula

This illustration (b) diagrammatically shows a completely external biliary fistula cored from its bed in the liver and transplanted into a loop of jejunum brought up anterior to the transverse colon. In insert a may be seen the tissue to be cored out of the abdominal wall to preserve the fistulous tract. (As stated in the text, this procedure has not proved satisfactory, in terms of permanent patency.)

ternally. This operation was first proposed and employed on a patient by Dr. Hugh Williams at the Massachusetts General Hospital (Fig. 1).

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 1, 1948.
†From the Department of Surgery, Lahey Clinic.
†Director, Lahey Clinic.

hospital deaths in the entire series, an over-all mortality of 11.9 per cent. Of the 227 cases, 139 have been done since 1943, with 12 deaths, a mortality for this period of 8.6 per cent. In this experience we have employed nearly every known type of surgical approach to the problem, and Dr. Cattell and I

have now developed one that when it can be employed, as it can in most of the cases, offers the best prospect of a lasting, satisfactory result of all the measures of which we know. This method will later be published in a journal devoted entirely to surgery, but will be described in the latter part of this article in enough detail so that it will be available for any surgeon who might care to use it. These strictures have varied greatly in character, as well as in the number of previous operations the patients have had before coming to us, 2 examples of which are presented below, and they have likewise varied greatly in the measures employed in the attempt to restore the flow of bile into the intestinal tract. They have been complicated lesions and, in many cases, unsatisfactory to deal with. When one realizes, however, that portal cirrhosis or failing liver function (which is due to the biliary back pressure from stricture and the superimposed cholangitis so frequently associated with this lesion) will eventually result in death in all these cases unless something is done, it can be understood that however unsatisfactory many of these cases are, we must still endeavor to handle them surgically. This is done in an attempt to restore the patients, as can be done in some cases, to complete health and in others to be satisfied with merely prolonging their lives and making an unsatisfactory state a little more satisfactory than it would otherwise be.

CASE REPORTS

CASE 1 This patient had had a cholecystectomy in October, 1943. She had two repairs of her common duct, in 1943 and in 1944. In the latter part of 1944 a T-tube was inserted in her hepatic duct and in her common duct. She managed to get along with the T-tube until 1947, when she again became jaundiced and was operated on again, with the insertion of another T-tube. This T-tube passed down the common duct and into the duodenum in 3 months. In January, 1948, another T-tube was inserted, but in spite of this, it became blocked and this patient came to us for repair of her duct. (There had thus been six previous operations on the biliary tract of the patient before she came to the clinic.)

The patient was operated on by me on July 14, 1948. The hepatic duct was found with almost no cuff remaining, — that is, almost all the common hepatic duct had been destroyed, — and a Y-tube was inserted into the two limbs of the hepatic duct with less than 1 cm. of hepatic duct remaining. To this the mobilized demonstrated common duct, which had been freed from the pancreas and from behind the duodenum, was anastomosed, with at least for this brief time complete and satisfactory restoration of flow of bile into the intestinal tract. It is, of course, distinctly possible that an obstruction will again occur, but this experience does demonstrate how complicated these cases can be and yet how possible it is in many of them to re-establish the bile flow in spite of many (in this case, six) previous operations elsewhere upon the biliary tract.

CASE 2 This case likewise illustrates how complicated these cases may be. The patient had a cholecystectomy in 1947, at which time, either as a result of the acute gall-bladder condition for which the cholecystectomy was done or because of injury to the duct, a stricture resulted. Within the same year she was operated on again, and an anastomosis of the hepatic duct into the duodenum was done. This failed to function, and a further operation was done, again anastomosing the hepatic duct to the duodenum.

When this patient came to the clinic she was deeply jaundiced, and had had chills and fever for 2 months.

The hepatic duct was found with but a short stump. Its end was anastomosed to the common duct mobilized from the pancreas and behind the duodenum. After this anastomosis the patient became jaundiced, and a subdiaphragmatic abscess developed, which required drainage, but the jaundice failed to clear. She was sent home to die, with the idea that no more could be done. A further accumulation of the subdiaphragmatic abscess ruptured through the bronchus, and bile was discharged through the bronchus. A communication from her physician reported that it did not seem possible that she could recover.

Recent communications have indicated that the bronchial fistula has closed, bile is now draining into the intestinal tract, jaundice has cleared, and the patient appears to be at least temporarily recovering.

DISCUSSION

These cases are but illustrations of how complicated these problems can be and demonstrate some of the undesirable events that can be associated with the management of these extremely difficult problems.

This not inconsiderable experience with the management of injuries to the bile ducts has resulted in our arriving at quite definite convictions concerning what can and cannot be done and what can be expected with the various procedures that we have employed.

I should like to list in the sequence of their development the various measures that we and others have employed in the management of strictures of the bile ducts and to make comments on our satisfaction or dissatisfaction with each of them and particularly to mention, when we are dissatisfied, why dissatisfaction with the method has arisen.

This article attempts only to present the various types of operative procedures employed for the various conditions and to illustrate them diagrammatically.

It is my hope in presenting this experience of one surgical group with such a considerable number of these trying cases that I can at least bring up to date what has gone on in our experience and the plans for their management and discuss the futility of some of the plans that we and others have employed, with the reasons why we think they do not work, and present a new method that we have now used in enough cases and over a long enough period so that we can say that, when it is possible, it offers the best opportunity to obtain a satisfactory and lasting result.

The first plan of management of injuries to the bile ducts, that of transplantation of cored-out biliary fistulas, illustrated diagrammatically in Figure 1, was unsound in principle.

Although it is possible to transplant an external biliary fistula successfully into the jejunum or stomach, it can almost be said with certainty that at least in a predominating number of the cases, even though the fistula transplant is successful, it will ultimately contract, seal off and result in suppression of bile. It has been our experience with external fistulas that have been converted into internal fistulas by implantation into the stomach or

jejunum, and likewise with external fistulas that remain external, that the contraction of cicatricial tissue forming the wall of the sinus will ultimately be greater than the secretory pressure of bile, which in the beginning keeps it open, and that this will eventually, in either an external biliary fistula or an internal biliary fistula owing to an injury to the common or hepatic bile duct, result in spontaneous closure of the fistula.

External biliary fistulas made directly from the gall bladder in the presence of a stone or obstruction below the point of entrance of the cystic duct into the common or hepatic duct will of course, in most

accurate end-to-end anastomosis, it will result in permanent and satisfactory drainage of bile into the intestinal tract. Unfortunately, ascending infection, with resulting chills and fever and the ultimate development of cirrhosis, has occurred in too many of these cases to make it a satisfactory type of procedure. In addition, too many of these anastomoses however accurately they may be done in the beginning later contract and cicatrize down to the point where obstruction results. I have personally disconnected a number of such anastomoses done elsewhere that have contracted and

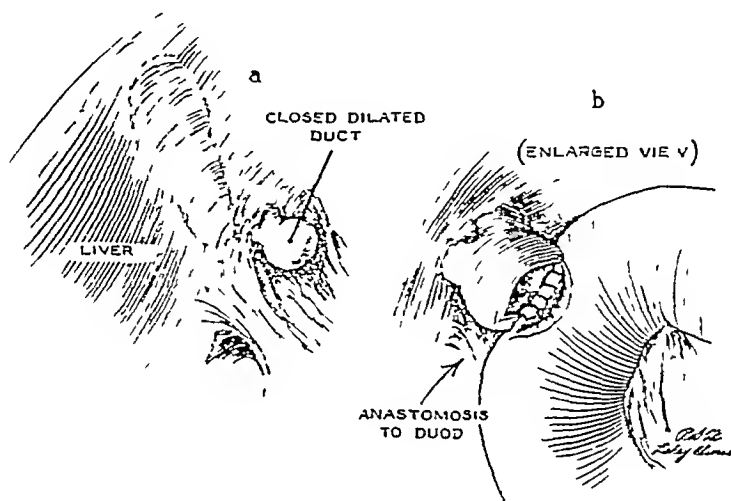

FIGURE 2. Anastomosis of Dilated End of Cat Hepatic Duct to Duodenum or Jejunum. The closed and dilated end of a cat hepatic duct is shown in a. The end has sealed over and complete obstruction has resulted. In b is shown the end-to-side anastomosis of the dilated and closed end of the hepatic duct to a loop of jejunum brought up over the transverse colon. Note how accurately mucosa-to-mucosa anastomosis can be done. (These structures are shown in enlarged detail to make them clearer.)

cases, drain on indefinitely because this is a mucous-membrane-lined fistula. When however a fistulous tract runs from the hilus of the liver at the region of the hepatic and common ducts after removal of the gall bladder and injury to the main bile ducts its length of cicatricial lined walls is so great that constriction with obliteration of the fistulous tract will result in almost every case. It is for this reason that this operation has been abandoned and is, we believe largely without value.

The next type of management of the patient with an injury to the hepatic or common duct resulting in an external biliary fistula and popularized by W. J. Mayo has been the direct mucosa-to-mucosa anastomosis (Fig. 2) of the dilated end of the cut hepatic duct to the duodenum or jejunum. If this operation, which is not difficult when the dilated end of jejunum is of considerable size, is done with

resulted in jaundice the patients coming to us for further repair and of a different type.

There have been a number of plans devised to overcome the ascending infection in repairs of this type one being the 'Y' loop in which something over a foot of blind jejunum is anastomosed to the end of the hepatic duct inserting the proximal loop of jejunum below this level to avoid ascending infection. Another suggestion has been the introduction of infolds in this segregated loop to discourage the ascent of jejunal contents through the anastomosed area to bring about infection. Still a final proposal has been the establishment of an entero-enterostomy below the point of the anastomosis of the end of the hepatic duct to the jejunum to side-track most of the contents of the jejunum and thus avoid ascending infection in the gall bladder.

have now developed one that when it can be employed, as it can in most of the cases, offers the best prospect of a lasting, satisfactory result of all the measures of which we know. This method will later be published in a journal devoted entirely to surgery, but will be described in the latter part of this article in enough detail so that it will be available for any surgeon who might care to use it. These strictures have varied greatly in character, as well as in the number of previous operations the patients have had before coming to us, 2 examples of which are presented below, and they have likewise varied greatly in the measures employed in the attempt to restore the flow of bile into the intestinal tract. They have been complicated lesions and, in many cases, unsatisfactory to deal with. When one realizes, however, that portal cirrhosis or failing liver function (which is due to the biliary back pressure from stricture and the superimposed cholangitis so frequently associated with this lesion) will eventually result in death in all these cases unless something is done, it can be understood that however unsatisfactory many of these cases are, we must still endeavor to handle them surgically. This is done in an attempt to restore the patients, as can be done in some cases, to complete health and in others to be satisfied with merely prolonging their lives and making an unsatisfactory state a little more satisfactory than it would otherwise be.

CASE REPORTS

CASE 1 This patient had had a cholecystectomy in October, 1943. She had two repairs of her common duct, in 1943 and in 1944. In the latter part of 1944 a T-tube was inserted in her hepatic duct and in her common duct. She managed to get along with the T-tube until 1947, when she again became jaundiced and was operated on again, with the insertion of another T-tube. This T-tube passed down the common duct and into the duodenum in 3 months. In January, 1948, another T-tube was inserted, but in spite of this, it became blocked and this patient came to us for repair of her duct. (There had thus been six previous operations on the biliary tract of the patient before she came to the clinic.)

The patient was operated on by me on July 14, 1948. The hepatic duct was found with almost no cuff remaining, — that is, almost all the common hepatic duct had been destroyed, — and a Y-tube was inserted into the two limbs of the hepatic duct with less than 1 cm. of hepatic duct remaining. To this the mobilized demonstrated common duct, which had been freed from the pancreas and from behind the duodenum, was anastomosed, with at least for this brief time complete and satisfactory restoration of flow of bile into the intestinal tract. It is, of course, distinctly possible that an obstruction will again occur, but this experience does demonstrate how complicated these cases can be and yet how possible it is in many of them to re-establish the bile flow in spite of many (in this case, six) previous operations elsewhere upon the biliary tract.

CASE 2 This case likewise illustrates how complicated these cases may be. The patient had a cholecystectomy in 1947, at which time, either as a result of the acute gall-bladder condition for which the cholecystectomy was done or because of injury to the duct, a stricture resulted. Within the same year she was operated on again, and an anastomosis of the hepatic duct into the duodenum was done. This failed to function, and a further operation was done, again anastomosing the hepatic duct to the duodenum.

When this patient came to the clinic she was deeply jaundiced, and had had chills and fever for 2 months.

The hepatic duct was found with but a short stump. Its end was anastomosed to the common duct mobilized from the pancreas and behind the duodenum. After this anastomosis the patient became jaundiced, and a subdiaphragmatic abscess developed, which required drainage, but the jaundice failed to clear. She was sent home to die, with the idea that no more could be done. A further accumulation of the subdiaphragmatic abscess ruptured through the bronchus, and bile was discharged through the bronchus. A communication from her physician reported that it did not seem possible that she could recover.

Recent communications have indicated that the bronchial fistula has closed, bile is now draining into the intestinal tract, jaundice has cleared, and the patient appears to be at least temporarily recovering.

DISCUSSION

These cases are but illustrations of how complicated these problems can be and demonstrate some of the undesirable events that can be associated with the management of these extremely difficult problems.

This not inconsiderable experience with the management of injuries to the bile ducts has resulted in our arriving at quite definite convictions concerning what can and cannot be done and what can be expected with the various procedures that we have employed.

I should like to list in the sequence of their development the various measures that we and others have employed in the management of strictures of the bile ducts and to make comments on our satisfaction or dissatisfaction with each of them and particularly to mention, when we are dissatisfied, why dissatisfaction with the method has arisen.

This article attempts only to present the various types of operative procedures employed for the various conditions and to illustrate them diagrammatically.

It is my hope in presenting this experience of one surgical group with such a considerable number of these trying cases that I can at least bring up to date what has gone on in our experience and the plans for their management and discuss the futility of some of the plans that we and others have employed, with the reasons why we think they do not work, and present a new method that we have now used in enough cases and over a long enough period so that we can say that, when it is possible, it offers the best opportunity to obtain a satisfactory and lasting result.

The first plan of management of injuries to the bile ducts, that of transplantation of cored-out biliary fistulas, illustrated diagrammatically in Figure 1, was unsound in principle.

Although it is possible to transplant an external biliary fistula successfully into the jejunum or stomach, it can almost be said with certainty that at least in a predominating number of the cases, even though the fistula transplant is successful, it will ultimately contract, seal off and result in suppression of bile. It has been our experience with external fistulas that have been converted into internal fistulas by implantation into the stomach or

As the result of this experience with rubber and vitallium tubes and, in addition, tubes of bouncing clay introduced to bridge the gap when sections of the hepatic and common ducts have been injured or removed, it is our belief that when they must be introduced one must assume that certainly in most cases they will eventually plug and later require removal and replacement.

The next proposal in order of sequence was that suggested by Dr. Arthur W. Allen² in 1944—that is, the employment of a turned-in, single loop of jejunum to anastomose to the hilus of the liver about the cut end of the hepatic duct (Fig. 4). Although we have had no experience with this operative procedure, we have little hope but that what happens with cut hepatic ducts will happen when the end of the hepatic duct is implanted in the turned-in end of a loop of jejunum: the end of the duct will cicatrize, close and result again in complete obstructive jaundice. I have had the opportunity to disconnect one of these, which had been done in another part of the country, and found that this was what had taken place. We have seen so many of these patients who come to us

of at the last meeting of the American Surgical Society by Dr. Alfred Blalock, is the anastomosis of the amputated end of the left lobe of the liver to the jejunum in the hope that the drainage from the right hepatic duct can be backed up along the left hepatic duct and that, by means of this reversed flow of bile through the left hepatic duct, the entire right and left lobes of the liver can have

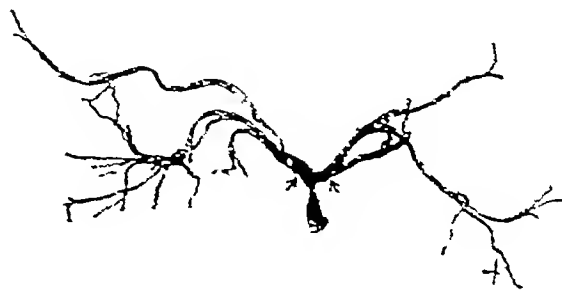

FIGURE 6 Corrosion Specimen of the Bile Ducts in Which Plastic Material Is Introduced into the Bile Duct and the Lesser Omentum Digested

In such specimens it may be observed that the biliary passages of the left lobe of the liver are quite complete and separate from the right lobe and probably, considerably without connection. As stated in the text and shown in Figure 5, unless enough hepatic duct remains uninjured, bile cannot descend from the right duct up the left, and as stated in the text when enough hepatic duct remains to permit this it is possible in most of the cases by the plan here presented to anastomose the mobilized common duct directly to the stump of the hepatic duct and thus to retain the sphincter and obtain mucosa-to-mucosa healing.

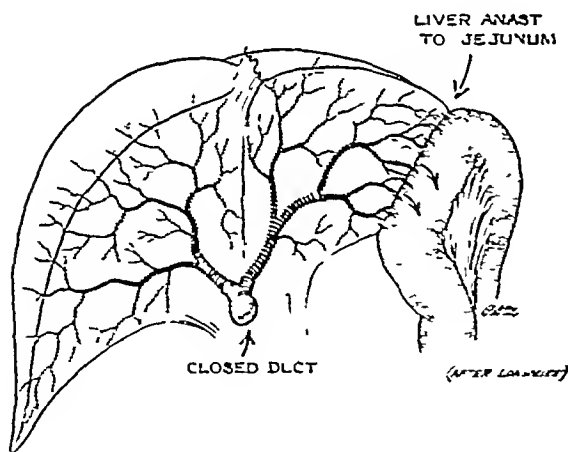

FIGURE 5 Plan of Amputating a Portion of the Left Lobe of the Liver and Anastomosing It Directly to a Loop of Jejunum in the Hope That the Bile from the Right Lobe Will Descend the Right Hepatic Duct, Ascend the Left Hepatic Duct, and Thus Drain Directly into the Jejunum

Note the closed end of the hepatic duct, which may be long enough or possibly to come down the right hepatic duct and up the left hepatic duct to make this procedure feasible.

after having had several previous operations in whom only a scarred intrahepatic short stump of common hepatic duct remained that we are very skeptical that the suture of this loop of jejunum about the open duct will result in permanent patency of the end of the hepatic duct in the presence of so much scar tissue in its walls.

A recent novel proposal made by Dr. W. P. Longmire, Jr., of Johns Hopkins Hospital, and spoken

their biliary drainage discharged into the jejunum (Fig. 5 and 6).

We do not have much hope for the success that may follow this procedure because as we have seen them in so many of these cases, as shown in Figure 5, the common hepatic duct will have been destroyed up to the point where the two main hepatic ducts draining the right and left lobes of the liver (Fig. 6) will be all that remains of the hepatic ducts.

Dr. W. A. Meissner, of the pathological laboratory of the New England Deaconess Hospital, has made corrosion specimens of the hepatic ducts of livers for us, and if one sees these it will be evident that for this proposal to function it would be necessary that there be a fair length of common hepatic duct into which the right hepatic could discharge and then pass up in the reverse direction to the left hepatic duct (Fig. 6). We know from our experience in operating on so many of these patients that this is often not the case and that, as mentioned above, the loss of substance of the hepatic duct, with the multiple operations that many of these patients had had, has been so great that little or no common hepatic duct remains and so there is no communication that can be employed between the right and

None of these plans have been satisfactory, and one can only say that although these types of anastomoses do drain bile, in most of the cases the results are seriously compromised by the repeated attacks of cholangitis that accompany them.

The next stage in the development of the surgical management of injuries to and strictures of the hepatic and common duct was the introduction of

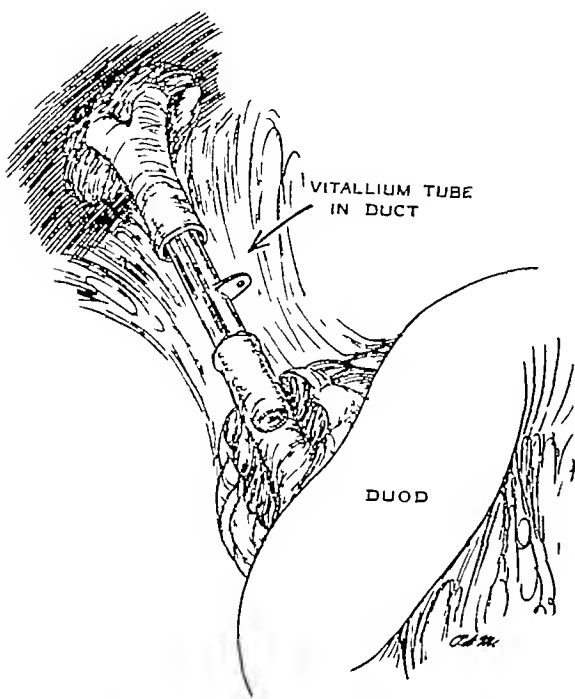

FIGURE 3 Plan of Introducing a Vitallium Tube, as Shown in This Case, but in Others Sections of Rubber Tube or the Material Called Bouncing Clay Have Been Employed, the Tube Serving as a Substitute for the Lost Segment of the Common or Hepatic Duct

It is to be recalled that the scar tissue about this tube is wrapped around the tube to enclose it tightly and in the hope that it will be supported as a substitute for the missing section of duct. Note the projecting tab on the vitallium tube, which recalls that these tubes have passed completely through the common duct, through the sphincter of Oddi into the duodenum, in spite of the presence of such an offshoot that one would expect would hold the tube in place permanently.

segments of rubber or vitallium tube, as shown in Figure 3, the upper end being introduced into the stump of the hepatic duct, the lower end into the stump of the common duct and such material in the form of scar tissue and omentum as could be obtained wrapped around the missing segment to provide covering for the implanted tube within the two cut ends of the ducts.

The drawbacks to this procedure have been two in most cases the tube has been passed in spite of the use of all types of tubes in attempts to make them remain in place — whenever the tube has been passed, it has been our experience that in practically all cases the remaining cicatrized area, unlined with

mucosa as it is, no longer stays open but eventually, as does the external biliary fistula, contracts, closes and again produces complete biliary obstruction, in addition, many of these tubes, even though they remain in place, eventually become plugged and require removal and the reinsertion of another tube. As many as four different tubes have been introduced in some of our patients on whom this procedure was employed, the periods varying from one to three years. The longest period a tube, introduced in such a case with a complete defect between the cut end of the hepatic duct and the common duct, has drained without jaundice has been seven years. This patient eventually died of cirrhosis, at autopsy the tube was found plugged, and in all probability the tube had plugged early, and bile was being passed satisfactorily around it.

Soon after this the employment of a vitallium tube in place of rubber tubes was proposed in the hope that because vitallium is well tolerated by the tissue, being a nonelectrolytic metal, these tubes would not plug. It was hoped that these tubes (Fig 3), which possess a tab or flange sticking out from their longitudinal wall, would not be passed into the duodenum. Neither of these hopes has been fulfilled. Vitallium tubes have, in our experience, plugged just about as often as have rubber tubes, and, surprising as it may seem, the

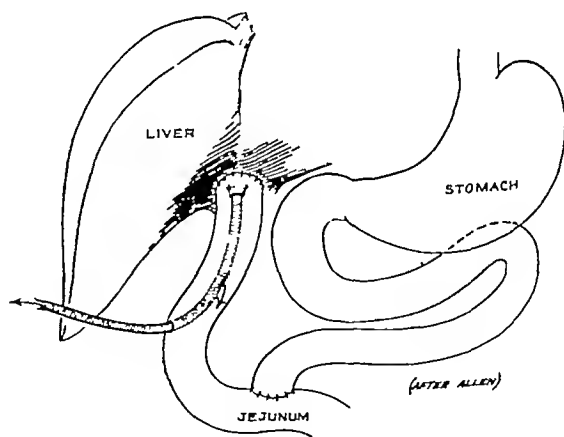

FIGURE 4 Method of Employing a "Y" Loop of Defunctionalized Jejunum, the End of Which Has Been Turned in and Sutured to the Hilus of the Liver about the Opening into the Cut End of the Hepatic Duct

vitallium tubes even with the good-sized flange that is attached to them have several times passed through the common duct, through the sphincter of Oddi into the duodenum and stricturing of the segment that they replaced has followed in most of the cases in which the tube has passed. Furthermore, like rubber tubes, many of these vitallium tubes have had to be removed and replaced because of their being plugged.

patency of the sutured duct. We have left these T-tubes in place up to a year and longer in certain cases, to ensure patency at the line of suture and to permit good union of the mucosal surfaces. We have now for a considerable period introduced these T-tubes through a slit either in the hepatic duct above the line of anastomosis when the hepatic duct is sufficiently long or through the common duct below the line of suture when the hepatic duct is short (Fig 7). This permits one limb of the tube to pass through the point of sutured duct and permits the withdrawal at the end of a year of the

repair that no hepatic duct at all remains. In such cases it has been necessary to introduce a small section of Y-tubing with one limb in each intra-hepatic duct, the other passing down into the mobilized common duct, and to do a direct anasto-

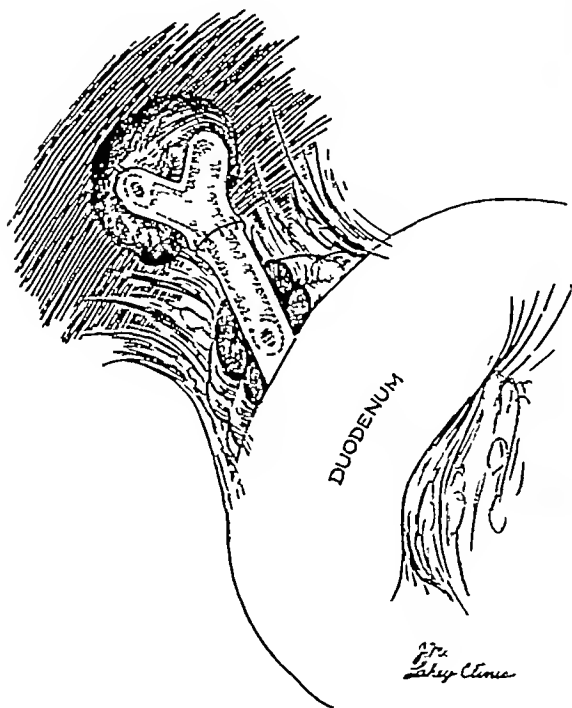

FIGURE 8 Diagrammatic Illustration Demonstrating How It Is Necessary to Employ a Y-Tube with One Limb in the Right and One in the Left Branch of the Hepatic Duct to Make Complete Anastomosis Possible

In many of these cases it has not been possible to introduce a T-tube below because it would be necessary to place the upper limb of the T-tube in either the left or the right hepatic duct. This line of procedure has the disadvantage of requiring that the tube be left in place, with the possibility and not improbability that it will later plug and require replacement. In the corrosion specimen (Fig 6) arrows have been placed on the right and left hepatic ducts to indicate the height to which destruction of the hepatic ducts has taken place in many of the patients who have been subjected to repeated attempts to repair the ducts

T-tube without injury to the line of anastomosis or without producing the narrowing that occurred when cicatrization of the aperture took place at the point of the tube withdrawn through the suture line.

In the management of complicated bile-duct problems of this sort many of these patients have had so many previous unsuccessful attempts at

FIGURE 9 Plain Film of the Abdomen in a Case in Which It Was Necessary to Implant a Y-Tube (of Boaring Clay), as Shown Diagrammatically in Figure 8

mosis about it on the indwelling tube (Fig 8 and 9).

This is less desirable than the introduction of a T-tube for a year because if blockage of the indwelling T-tube occurs it can frequently be overcome by the introduction of ether or by irrigation with saline solution. We have had relatively little trouble with the T-tube blocking, but when one leaves a Y-tube in, as shown in Figure 8, with no external drainage, there are often cases in which plugging of the tube occurs, and re-operation becomes necessary if another tube is introduced to bring about maintenance of drainage.

In doing these end-to-end anastomoses all sorts of unsatisfactory conditions are bound to arise. An occasional result in our experience — and one about which we know of nothing to do — is that in which the lower end of the duct can be found but is of such small, atrophic character that it is impossible even after it has been mobilized to dilate it up to a size adequate for the introduction of a T-tube of satisfactory caliber. In still other cases there will be so much destruction and scarring of the pancreas, the common duct and the region about the duodenum that it will — very rarely in-

left hepatic ducts by means of which bile from the right lobe of the liver could be made to ascend through the left hepatic duct and thus discharge into the intestine as the cut end of the left hepatic duct in the severed left lobe of the liver is implanted into the jejunum

We are very skeptical that this ingenious proposal will be of any great value. We believe that it could

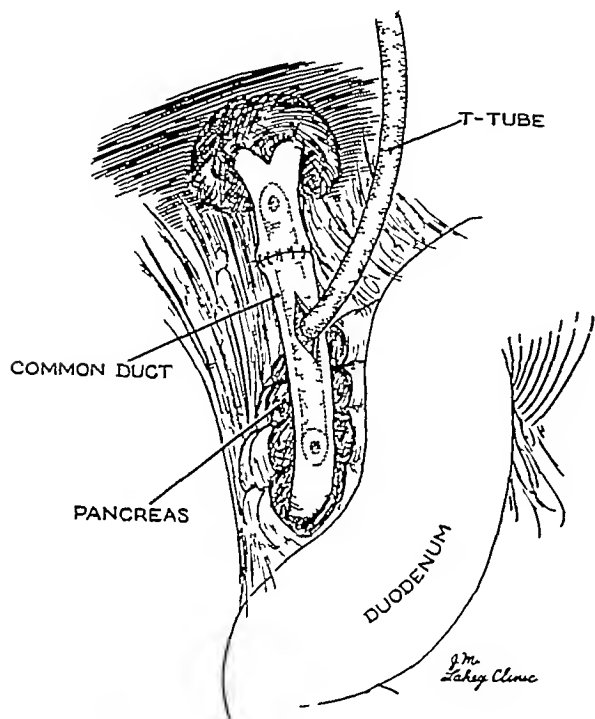

FIGURE 7 Plan Devised by Drs. Cattell and Lahey, with the Duodenum Rolled to One Side, the Pancreas Split, the Retro-duodenal and Intrapaneatic Common Duct Exposed Mobilized and Approximated to the Stump of the Hepatic Duct

Note the demonstration of the intrahepatic portion of the duct and, in addition, the method of introducing a T-tube through an incision in the common duct below the line of suture so that one limb extends through the anastomosis and the anastomosis can be made accurately and completely around the entire circumference of the duct. Note also, diagrammatically, how often it is necessary by means of fulguration to dissect the scarred end of the hepatic duct out of the hilus of the liver and in many cases to carry the dissection up sufficiently so that both individual hepatic ducts, right and left, are demonstrated

work only when an adequate stump of hepatic duct remains, as shown in Figure 6, and, even then, we believe that the proposal of direct duct anastomosis, which was devised by Dr. Cattell and myself and which is discussed below, will then be a possible and much more satisfactory approach to the problem

In seeking for a method that offered more satisfactory prospects of restoring the excised or damaged common and hepatic ducts to normal and thus the discharge of bile in the duodenum by a normal channel, we have visualized two things that would be

necessary to bring about satisfactory function in the discharge of bile from the biliary radicals in the liver into the duodenum. One, outstandingly, is the necessity for the preservation and functioning of the sphincter of Oddi. It is only by the preservation of this apparatus that one can be assured of the absence of ascending infection, chills and jaundice and their effect upon the liver itself. The other requirement is that permanent restoration of the main bile channels can be accomplished only by direct end-to-end anastomosis of the injured or severed duct so that there is accurate mucosa-to-mucosa approximation, as is necessary in restoration of any of the mucous-membrane-lined structures in the body that convey either fluid or liquid

In the course of a large experience with mobilization of the duodenum and demonstration of the lower end of the common duct where it passes through the head of the pancreas and into the duodenum as part of removing the duodenum and duodenal ulcers within the duodenum adherent to the bile ducts, we have learned to mobilize the duodenum by mobilizing its external wall and to demonstrate the portion of the common duct behind the duodenum and within the pancreas by splitting the pancreas about the common duct. This directed our attention to the possibility of mobilizing this portion of the common duct, which by its location within the head of the pancreas and behind the duodenum, is usually protected from injury no matter how many operations are done for repairs on cut or crushed ducts

It was through familiarity with this procedure and with Dr. Cattell's experience with resections of the pancreas that we became interested in so mobilizing the duodenum and so visualizing the lower end of the common duct behind the duodenum and in the head of the pancreas that when an adequate amount of hepatic-duct stump remains, as it usually does, direct end-to-end anastomosis could be accomplished

This procedure has now been done in 43 cases over five years, and we have deferred reporting it as a method until we had had enough experience with it to suggest its possibility and be certain of its feasibility in at least a very high percentage of cases of injury or stricture of the common and hepatic ducts

It is surprising, when the uninjured portion of the common duct that runs through the pancreas to enter the back of the duodenum is mobilized and delivered from its oblique position behind the duodenum, how often this end can be made to approximate to the end of the hepatic duct without tension, even when a considerable portion of the common or hepatic duct has been destroyed (Fig. 7)

When we first did these duct anastomoses the T-tube was brought out directly through the line of anastomosis. We have considered it necessary in these cases to introduce such a tube to maintain

hospitals after the war and that a major reorganization of the conditions of medical practice would be needed. Conferences between the medical profession and the Minister of Health in Mr Winston Churchill's Coalition Government resulted in tentative agreement for the provision under the auspices of the Minister of Health of a service to cover all aspects of medical care for almost the whole nation.

The general election of 1945 placed the Labour Party in power, and this agreement was ostensibly scrapped by the new minister of health, Mr Aneurin Bevan. He announced that he would present a measure to Parliament without bothering to have full discussion with any representative of the British Medical Association, and the dispute with the British medical profession that resulted has received wide publicity. It was a foregone conclusion, however, even three and a half years ago before Mr Bevan took over, that the central government would be in control of the conditions of medical practice. All the major hospitals have continued to receive indispensable financial support from the Government since the war, the use of this money being subject to continuous governmental surveillance. By virtue of these facts the conditions under which consultant practice is carried on in hospitals have been but little changed since the latest act became operative on July 5. Hence this is not a premature point at which to judge the status of the physician and his hospital work in England. Further, since the general practitioner's type of panel practice for the past thirty-six years on over a third of the population was already extended during World War II to over half the population, one may extend these accumulated data to help in analyzing his present situation with almost the whole nation on some panel.

As was to be expected there were temporary dislocations and points of stress after medical care became completely free on July 5, but no mention has been made of these in the ensuing comments. The attempt has been to refer only to facts pertinent to the long-range trends. Some of the problems that have arisen are a consequence of current shortages and Government regulations in fields other than those strictly medical, these appear to present a more chronic, self-perpetuating source of trouble and are noted below.

The effects of the British National Health Service may be considered first from the standpoint of the general practitioner and secondly from that of the specialist, or consultant, as he is termed in England.

THE FAMILY DOCTOR

The physician in general practice in England today is swamped by a volume of work that makes it possible for him only rarely to take a clinical history or make a thorough physical examination in the fashion that is attempted in this country.

According to computations based on the experience with panel practice before the war, one may estimate that the British general practitioner must now in the course of a single day see in his office and in visits to homes an average of at least 50 patients if he has the average panel of 2000 persons — or 100 patients if he has the maximum panel of 4000. These figures are based on the knowledge that the prewar panel patients, largely men, each averaged five visits a year to their physicians¹ and on actuarial statistics^{2, 3} that demonstrate almost twice the morbidity in women who (as well as the men) are now insured in Great Britain. Such a staggering load permits the physicians but a few minutes with each patient. The tentative impression is that this expected volume of work is actually exceeded at present.

There is 1 physician per 875 inhabitants in Great Britain⁴ as compared with about 1 per 720⁵ in this country. The load in England appears to arise not from a great shortage of physicians there but because the physician is expected to carry out many functions that Americans would not consider a part of his task. Many people with minor complaints — inconsequential gastrointestinal upsets and upper respiratory infections — present themselves. Even though they may recognize the triviality of the disorder, they often wish to obtain medication, which is provided free of charge with the doctor's prescription, so that they sit about in his office and wait for a handout. This availability of free conversation with the doctor and free medicine also is considered to multiply the number of mild psychoneurotic and hypochondriac patients who appear.

The Labour Government's innumerable restrictions on the lives of every person also result in countless daily appeals to the doctor for escape. The employee may not be absent from work without a valid excuse, and a note from the physician is the easiest kind of justification to present. The worker tells his doctor that he has had diarrhea for two or three days and has not been at work, and the doctor signs a form he has ready for the occasion certifying to the man's illness. This has become such a standard practice that physicians have incurred the contempt of many employers, but the unhappy physician between the fires of labor and management will naturally accede to the laborer's wish. Otherwise, the patient may request a house visit the next time and present the doctor with the evidence for his complaint if it is bona fide, or he may change his name and with it his capitation fee per annum to another physician's list. And since labor is able to outvote management, the doctor's plight is likely to worsen rather than improve if he does not play this game. Many people who wish to evade the food-rationing restrictions seek a doctor's certificate of medical need for more eggs, meat, cheese, milk and so forth. There appears to be a limitless

deed, but occasionally — be impossible to find enough duct, even though it is completely mobilized, to get the ends together. Still another complication, which has been the most trying one we have had to deal with, is the fact that so often repeated, unsuccessful attempts at repair will have so destroyed the common hepatic duct that there will only be the separated intrahepatic right and left ducts. Even beyond this, Dr Cattell has successfully anastomosed the left hepatic duct when it was impossible to find the right because of the depth of scarred duct within the liver. In such cases atrophy of the right lobe and enlargement of the left have taken place, with adequate maintenance of liver function. Still another complication that has bothered us in these trying operations has been opening of the portal vein in the course of searching for either the lower end of the duct or the end of the hepatic duct within the hilus of the liver. In these cases we have successfully controlled such bleeding by suture of the portal vein, but this has resulted in the necessity of terminating at least temporarily further search for the duct.

SUMMARY

Experiences in the surgical management of 227 patients with benign strictures of or injuries to the bile ducts are presented. The development of the different methods employed since the publication of our first paper on the subject in 1923 is outlined, and the disadvantages of all these measures are discussed. A new plan, which has been employed for a minimum of five years in 43 cases, results in preservation of the sphincter of Oddi and direct mucosa-to-mucosa anastomosis when it can be employed and offers, it is believed, both the most logical approach to the surgical management of this up to now discouraging lesion and the best prospect of the permanent discharge of bile from the liver into the duodenum without complications that are involved with other procedures.

RECENT IMPRESSIONS OF MEDICAL PRACTICE IN GREAT BRITAIN

WILLIAM H. SWEET, M.D.*

BOSTON

MANY physicians have hitherto regarded only with casual interest the controversy over the organization of medical practice in this country. I, myself, for example, have assumed that a faculty member of the staff of a teaching hospital could be little affected by any of the bruited changes — a notion that has been sharply challenged by observations of the current status of physicians in this and other categories in Great Britain. Severely jarred in my complacency by what I have seen during a recent period of work on one of the active services of a large English hospital, I am recording what are admittedly only a series of impressions rather than a careful statistical study. British physicians in all types of work have been profoundly affected by the legislation of His Majesty's Government, and we here would do well to realize that none of us are necessarily immune to the consequence of radical departures in medical administrative procedure.

The latest of the items of legislation governing medical practice in Great Britain finally came into force on July 5, 1948. It is important to recognize, however, that this is only the culminating step in a series of laws that began with the National Health Insurance Act, starting in 1912. This initial legis-

*Assistant professor of surgery, Harvard Medical School; lecturer in neurosurgery, Tufts College Medical School; associate visiting neurosurgeon, Massachusetts General Hospital.

lation set up a system of compulsory health insurance for nearly all wage earners and resulted in the provision of the services of a general practitioner and of the medicines he prescribed for approximately a third of the population. No care of a medical specialist and no hospitalization were included in this measure. The Local Government Act of 1929 increased the number of hospital beds operated by the Government, and the Voluntary Hospitals Paying Patient Act of 1936 opened these institutions to the entire population whether able to pay or not. During World War II the bombing of civilians and large cities led to the construction by the British Government of numerous hospitals outside the cities and the employment either part time or full time of nearly all the physicians remaining outside the armed forces. The doctors were utilized in, and the hospitals were operated by, the British Emergency Medical Service under the Minister of Health. In addition to this organization the Ministry of Health during the war contributed notable financial support to the so-called voluntary or privately operated and endowed hospitals of the country, which included the major teaching hospitals of the medical schools. The wartime level of taxation and the rising costs of living made it apparent to all during the war that there would be insufficient voluntary donors to support the privately endowed

of the area long after the physician had finished his postgraduate training in the hospital

Three years later the same consultant, now recognized as the most outstanding member of the medical faculty of his university, is like his colleagues working under many handicaps. His eminence led his university in 1944 to promise him an institute, to be erected forthwith as three temporary one-story buildings without basement, on empty space already available in the hospital grounds. By 1948 one of these has barely been started, the other two are less than half finished. Yet this is virtually the only hospital construction under way since the war in a city of a million inhabitants. The details of the numberless delays, which have already dragged out to over four years a construction that should have been a four-month task, furnish a monotonous account of the hamstringing of every energetic person by the requirement of a governmental permit for every item of material, for all the precursors of each of the materials, for the transportation of the precursors and the materials, for the allocation of the appropriate type of labor to handle the precursors of the materials, the materials and their actual construction and so on *ad nauseam*. These appear to be the advantages of completely centralized integrated control, so that first things can be done first. The activities of the most distinguished worker in this hospital continue to be carried on with the same primitive facilities that burden the remainder of the staff. All this is despite the fact that the Minister of Health has been for years in charge of all housing as well as hospital construction and might reasonably have been expected to provide for a little work on hospitals.

It is perhaps pertinent at this point to draw attention to the exclusive power of the Minister of Health under the present act to appoint all members of all medical boards governing all aspects of medical practice in the whole country, including the teaching hospitals. There is no grant *en bloc* of funds to units that otherwise remain independent of the Government, such as occurs now in relations between United States federal agencies and research groups, and represents the British method of support of its universities (entirely apart from the medical schools). Under a system in which the autonomy of the local group is preserved, tasks might well be completed in a reasonable time instead of dragging on in such a preposterous fashion for years.

The paucity of men of consultant status, serious before the war in England, has not been alleviated, despite the fact that increasing knowledge makes the need for them greater. The waiting list on the neurosurgical service on which I worked was such that a patient with a presumed brain tumor had to wait about three months before he could enter the hospital. Numbers die before they reach the top

of the list. There was virtually no time available to operate for the relief of pain on patients with malignant neoplasms — no matter how good their prognosis for a long useful life if free of pain.

The volume of nonmedical duties falling to the consultant, although not so overwhelming as that of the general practitioner, is still oppressive because all the factors creating such duties operate on him as well, albeit to a lesser degree. In the Regional Medical Board meetings the agenda drawn to my attention were largely cluttered with items of minor business administration, such as approving a new heating plant for an outlying hospital. To these the most senior and capable medical members of the community found themselves compelled to devote whole afternoons. I am told that they dare not resign from these boards, though, lest control be gained by men who would make the practice of medicine a series of acts of obedience to such fiat, proclamations, directives and commands as the board might see fit to dispense.

A minor example of the advantages of bureaucracy was my experience of applying to the appropriate segment of the Ministry of Health in Whitehall for certain special instruments to perform an operation by a hitherto untried method. The whole project was explained in some detail, and the letter of request received a prompt postal reply promising consideration. Eight months later, long after I had obtained the needed articles from a private source, I had a letter declining the request because the instruments were not part of the usual neurosurgical setup.

One should mention that men in hospital training for consultant posts are to be paid salaries after the internship period that are somewhat higher than those paid by the major teaching hospitals in this country. The financial support at this crucial period in a young man's life permits merit to be a more significant factor in determining selection for advanced training and is a feature of the British system that might well be emulated in this country.

No systematic discussion of salaries to be paid to the various categories of practicing physicians will be attempted here, final decision regarding the salary scales for consultants has not even been made although the profession has been at work since July 5 under the new regime. However, the present salaries of three colleagues and personal friends bear mention. They are consultants with extended complete postgraduate training in a surgical specialty, and they now hold full-time appointments in major hospitals. Each of these men with a family is paid about \$2500 per year after income tax deductions, and this is a representative income for such men under forty years of age throughout England. This permits each a scale of living approximately similar to that which one would obtain in this country on such an income, but the startling fact

type of such requests for special housing, heating, transportation, domestic equipment and so on *ad infinitum*. The building of an additional room on a house, the purchase of more fuel, or more electric heat, the ownership of a car or more gasoline for it—even the buying of a hot water bottle—require governmental permits, or are facilitated by governmental priorities, one avenue to which is a physician's certificate of medical need. Another group of cases in which the doctor acts more as a referee than as a healer is the workmen's compensation group. Although that exists in this country, too, there is a special feature in Great Britain that tends to make the workman dissatisfied since the state and not he himself pays the doctor's bill, he is likely to regard the physician not as his advocate in the dispute but as that of the state from which he is attempting to wrest more money. There is virtually no neutral body of medical men that is employed neither full time nor part time by the state from whom he can secure an opinion unbiased by such employment, so that he may seek the opinions of many doctors, finally utilizing the report of the one who would give him the most. There is still another group, the war veterans, over whose demands for special funds the physicians in Great Britain must act as umpire. The war veteran in this country is entitled to compensation for any medical disability he may develop, only if he is unable to pay for the treatment himself, but the British veteran is so favored only if the disability arose as a direct consequence of his war service. The burden of testifying to this thorny problem falls on the doctor.

Another handicap imposed on the general practitioner is the extreme paucity of special diagnostic facilities at his command. Even routine blood counts are difficult for him to obtain—not to mention quantitative blood chemical analyses and bacteriologic or roentgenographic studies. Almost the only clinicopathological and x-ray departments are those in hospitals, and these are already swamped with work from the hospital itself. The directors of these departments suspect, doubtless rightly, that if the general practitioner were able to call on them at will, many would abuse the privilege, writing out the requests for laboratory work with the same lavish hand that dispenses excuses for absenteeism. The conscientious student of his cases thus has his ardor dampened by the fact that as soon as a patient with an interesting problem appears he must refer that person to a consultant.

The Labour Government announces that it is proposing to set up so-called health centers in which several doctors will have their offices and at which there will be a diagnostic laboratory. No such centers have yet been built, nor are any being projected for the immediate future. It is pertinent to contrast this situation with the type of practice so prevalent in this country for some decades in

which groups of doctors have organized themselves on their own initiative to provide not only laboratory but also roentgenologic studies for their patients, along with specialized consultant services within the group.

The fact that house calls are now free in Great Britain removes one useful restraint from the type of patient who nurses his complaints in silence all day and then decides at midnight that he had better call a doctor. Failure of a physician to answer an emergency call not only may unfairly lose him the patronage of the patient but also is the basis for serious disciplinary action by the General Medical Council or other appropriate agency. One painstaking physician, fearful lest a real emergency be overlooked, has become so exhausted and distraught answering futile night calls that a psychiatrist has had to recommend a protracted period of vacation.

The so-called patient's free care extends to the dispensing of such needed appliances as braces and eyeglasses. He tries in the first instance to get from the general practitioner whatever arch supports or girdles may appear a handy thing to have about. But if the patient is balked at this level the opinion of a consultant may be demanded. In an outpatient clinic in which I was working a man appeared with an excellent result following the removal through a small laminectomy of a midthoracic cord tumor. He put on a little show for us in an effort to get a back brace, making it clear that he thought he was now entitled to this, and meant to have it. A further consequence of the fact that the Government is now the only purchaser of prostheses and braces is the driving out of business of all firms that the Minister of Health does not see fit to support. The doctor may order an appliance for his Health Service patient but he may not designate the firm that is to make it. This proscription is, for example, eliminating from the field one firm that is widely regarded as the best British maker of artificial limbs but is no favorite of the Labour Government.

THE CONSULTANT

And what of the lot of the consultant group? In 1945 a distinguished man in this category told me what striking improvements the reorganization would bring. For the first time the men in training would be paid adequately, and there would be enough of them to relieve the senior staff of onerous duties. The systematic planned utilization of the available personnel for the whole country could only lead to greater efficiency, necessary improvements would have only to be pointed out to the Minister of Health or his representative with direct access to the nation's Treasury and need not depend on the caprice of private gifts as it had before the war. Each major medical school would be the center of a region of the nation with its regional medical board, exercising a salutary continuing influence over the actual medical practice

selves with medical complaints, a discouraging additional number of them can apparently be counted on to do so. If the task of assessing the ability to lead an active life and the compensability of lack of enthusiasm therefor is to be extended to the entire population, the experience in Great Britain suggests that in this country extended ill feeling between the medical profession and other segments of the nation and a deterioration in the quality of medical care can be anticipated.

I have spent two years as an Oxford medical undergraduate, four years in London and Birmingham during the

war as a practicing surgeon employed by the Ministry of Health for most of this time, and a further recent period of work in England.

THE EFFECT OF SULFANILAMIDE ON SALT AND WATER EXCRETION IN CONGESTIVE HEART FAILURE*

WILLIAM B. SCHWARTZ, M.D.†

BOSTON

THE importance of the sodium ion in edema is well recognized. If a specific method were available for producing selective inhibition of the renal tubular reabsorption of sodium from the glomerular filtrate, it might well prove useful in the study and treatment of edema. A possible method is suggested by the studies of Pitts and Alexander¹. Under the conditions of their experiments they demonstrated that the renal tubules must make an active addition of acid to the glomerular filtrate to account for the acidity of the urine. The only source of acid large enough to account for the acidification of the urine was considered by them to be hydrogen ions derived from carbonic acid formed in the renal tubular cells. The loss of hydrogen ions by tubular excretion would require the absorption of base from the glomerular filtrate to maintain ionic equilibrium. To test this hypothesis these workers administered sulfanilamide, a specific inhibitor of carbonic anhydrase,² to dogs, presumably inhibiting the formation of carbonic acid in the renal parenchyma. After the administration of sulfanilamide the titratable acidity of the urine fell, and its pH increased. They postulated that reduction in tubular excretion of hydrogen ions had resulted from the inhibition of carbonic acid formation.

It appears that with sulfanilamide administration and decreased acid excretion, the disturbance in acid-base balance should result in failure to reabsorb fixed base from the glomerular filtrate. This loss of fixed base, if maintained, might be expected to lead to diuresis and to the loss of

edema. This paper is a preliminary report of studies that appear to substantiate this hypothesis.

METHODS

Three patients with severe congestive heart failure and fluid retention were selected for study. They were confined to bed and chair during the period of study and fed a constant diet containing about 2000 calories and about 300 mg of sodium. Daily fluid intake was constant. Digitalis was continued, but no ammonium chloride, mercurials or sodium-containing medications were permitted. Urine was collected for twenty-four-hour periods. A saturated solution of thymol in chloroform was employed as a preservative. Blood and urine chemical examinations were carried out in the usual fashion. Analyses of serum and urine for sodium and potassium were made with the Perkin-Elmer flame photometer, model 52A. Sulfanilamide was administered in amounts (4 to 6 gm per day) that were designed to keep the serum level at about 12 mg per 100 cc. The patients were weighed at the same time each day.

CASE REPORTS

CASE 1 The patient was a 48-year-old woman with a history of rheumatic valvular disease for 30 years and progressive cardiac decompensation for 15 years. Digitalis, a low-salt diet, ammonium chloride and semiweekly injections of mercurial diuretics had failed to prevent the accumulation of edema.

Physical examination revealed a thin, markedly dyspneic and orthopneic woman with cardiac enlargement, auricular fibrillation, mitral stenosis and insufficiency and aortic stenosis. There was marked venous distention (venous pressure equivalent to 240 mm of saline solution), fluid at the right lung base, enlargement of the liver to the umbilicus and a ++ pitting edema of the legs. She was continued on digitalis and placed on the constant diet and a fixed daily intake of 2000 cc. After 10 days, during which her weight and sodium output became stable, sulfanilamide was administered for a period of 7 days. The alterations in weight, urine volume and blood and urine constituents are given in Table 1.

is the relation of this annual earning to that of other groups in the country. It is indeed a smaller yearly income than that of a skilled mechanic in England working far less "overtime" than these men do. Every one of the skilled laborers in a factory of the father of one of these men has a higher income than he does after his fifteen years of higher education and postgraduate training and experience. The one man of the three who has no familial or other outside source of financial assistance cannot, of course, even afford to own a car. Two of the three men are actively exploring possibilities for leaving the country. One finds it difficult to avoid the impression that the medical profession in England is being burdened beyond the limit of tolerance.

THE PROBLEM

On the basis of the foregoing statements representing a catalogue of facts checked since the writing of this article by four different English physicians now in this country, a personal opinion will be ventured on the significance of these facts to the medical profession in the United States. In the first place, the sorry plight of our British colleagues appears to be due to their having been compelled to accept terms imposed by nonmedical members of the nation. Had they analyzed the defects in their system, presented a well conceived plan for improvements, and then stood fast against ill advised changes, the British people might now be receiving better care and the physicians might be happier about their working milieu. American physicians are or should be more familiar with the shortcomings in the present scheme here than anyone else. Unless they come up with a constructive program correcting these faults—perhaps even if they do—they can expect outside imposition of laws that, the British experience suggests, will at least in some aspects be detrimental to the best interests of the patient and his doctor.

The purpose of this article will be grossly misconstrued if it is considered an argument against any change in the present organization. The thesis is, on the contrary, that changes must occur and that the problem should be analyzed and the most logical type of reorganization effected.

One crucial feature of the difficulty in England, I believe, is that the responsibility for being healthy and economically self-sufficient has been shifted from the patient to his physician. I wish that the medical profession knew enough about human personality in health and disease to shoulder this responsibility, but I am convinced that I at least do not. When the political order in a country offers a helping hand to its ill citizens to assist them to struggle to their economic feet, the main burden of recovery should still fall on the patient. All physicians have seen striking examples of protracted convalescences that were being paid for by someone else, in contrast with brisk returns to activity in

patients with the same disorder who were determined to lead active lives again at the earliest moment.

There are three groups of cases in which the physician is at a peculiar disadvantage when the patient sheds the responsibility for getting well. In the first of these the person with a purely psychologic or simulated disorder is thought to have organic disease. In a manuscript currently in preparation I am including the case of a nurse who described in herself the symptoms of trigeminal neuralgia sufficiently graphically so that in five different major teaching hospitals she had a total of three alcohol injections and two operations on the trigeminal pathways, and yet after scores of hours of study by several examiners her physicians are still uncertain whether she ever had trigeminal neuralgia. This represents one of many organic disorders—for example, migraine, angina pectoris and other neuralgias—in which no objective signs of abnormality are necessarily present, and by virtue of which the patient without the disorder may consciously or unconsciously delude the physician with a convincing description.

The converse situation, in which an organic disorder is diagnosed as psychoneurosis by the physician, is also seen with disconcerting frequency. During the war I eventually saw several men whose presenting symptoms of their intracranial tumors were much more suggestive to their original medical officers of an inordinate desire to avoid combat than of any organic disease. One of the most unattractive features of medical practice in the armed forces is the frequent necessity of distinguishing the sick from those who complain of illness to avoid duty. The inefficient means for grappling with this problem is one of the causes for such a disproportionately large need for medical officers in the armed forces.

But the most difficult group of all is the much larger one of the patients with unequivocal evidence of structural malady in whom the question arises whether the complaints are excessive for the degree of anatomic damage present. How can the doctor, who unfortunately cannot feel the patient's pain, tell whether the headache that allegedly persists after a fracture of the skull or a back that goes on aching after a protruded intervertebral disk is removed should be treated by a prompt return to work or some financially compensable and less arduous tactic? I fear that even after hours of patient effort one emerges only with a guess.

In the present state of ignorance, if the doctor is to keep the good will of the community and his own self respect, he must do his best to see that his duties are so delineated, and the society so organized, that the number of cases in the foregoing three categories will be kept to a minimum. As soon as the political order or any other environmental feature makes it advantageous for any citizens to present them-

The effect on urinary sodium and potassium is shown in Figure 1. On the 3rd day of treatment the patient became slightly confused. This continued until 48 hours after the drug was discontinued, at which time she showed complete clearing of her sensorium. At no time was the confusion of sufficient severity to interfere with adequate co-operation. At the end of therapy the venous pressure had fallen to 170 mm of saline solution. The liver receded 6 cm, edema disappeared, and the amount of fluid in the chest diminished. The patient was no longer orthopneic and exertional dyspnea was decreased.

CASE 2 The patient was a 54-year-old woman with a history of rheumatic heart disease since the age of 12. Four years before admission she had suffered a severe episode of substernal pain followed by the onset of heart failure. Since that time she had grown progressively weaker and more dyspneic and had developed ascites. Treatment had consisted of digitalis, a low-salt diet and mercurial diuretics. Physical examination revealed a cachectic, dyspneic woman with marked cardiac enlargement, auricular fibril-

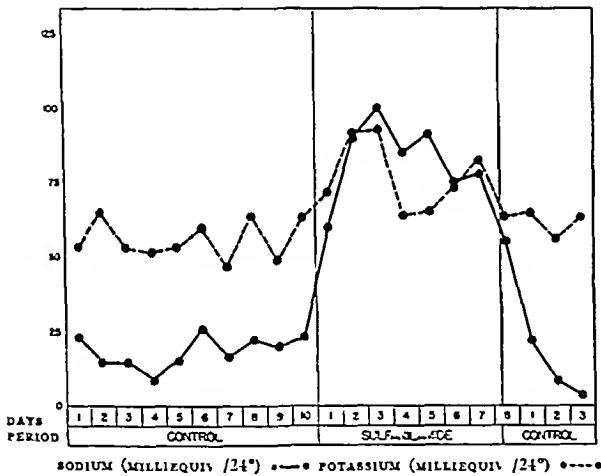

FIGURE 1 Effect of Sulfanilamide on Urinary Sodium and Potassium in Case 1

lation and mitral insufficiency and stenosis. Rales were present at both lung bases. The liver edge extended 6 cm below the right costal margin. There was no peripheral edema. During the first 16 days the patient was treated with a low-salt diet, digitalis, ammonium chloride and six 2-cc injections of mercury. This was accompanied by a weight loss of about 2 kg. The sixth injection of mercury was given on the 16th hospital day, and in the next 24 hours she gained 0.5 kg. She was then placed on the constant diet, and fluid intake was fixed at 1600 cc per day. After 4 days, during which her weight and sodium output became constant, sulfanilamide was administered. After 48 hours the drug was discontinued because of nausea, malaise and methemoglobinemia. During this period there was no appreciable change in physical findings. Changes in weight, urine volume, and blood and urine constituents are shown in Table 2, and the effect on urinary sodium and potassium in Figure 2.

CASE 3 A 64-year-old man gave a history of progressive heart failure of 3 years' duration. He had been known to have hypertension and coronary-artery disease for 8 years. Despite treatment with digitalis, salt restriction, ammonium chloride and mercurial diuretics twice a week, he had become markedly dyspneic, orthopneic and edematous. Physical examination revealed a dyspneic, orthopneic man with auricular fibrillation, fluid at the left-lung base and rales at the right-lung base. The liver edge was 8 cm

below the right costal margin, and there was +++ edema of both legs. The patient was continued on digitalis, placed on the constant diet and given a fixed 2000-cc. fluid intake. After 6 days, during which his weight and sodium output became stable, sulfanilamide was administered. This was well tolerated for 8 days, and during this time the dyspnea and

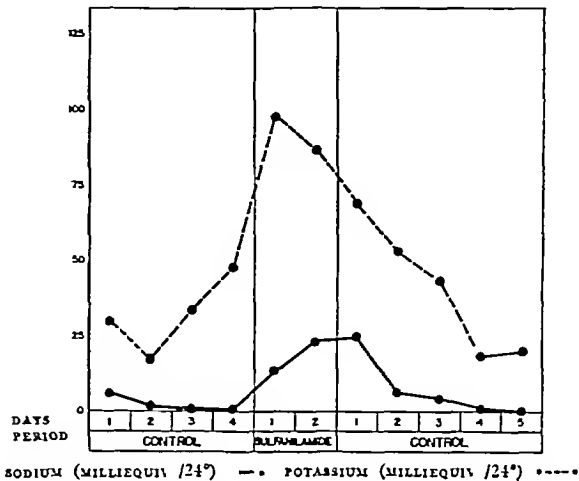

FIGURE 2 Effect of Sulfanilamide on Urinary Sodium and Potassium in Case 2

orthopnea improved markedly and the leg edema diminished to +. The liver decreased in size, and the venous pressure fell from 230 mm to 100 mm of saline solution. Changes in weight, urine volume, and blood and urine constituents are shown in Table 3, and the effect on urinary sodium and potassium in Figure 3. On the 7th day of treatment

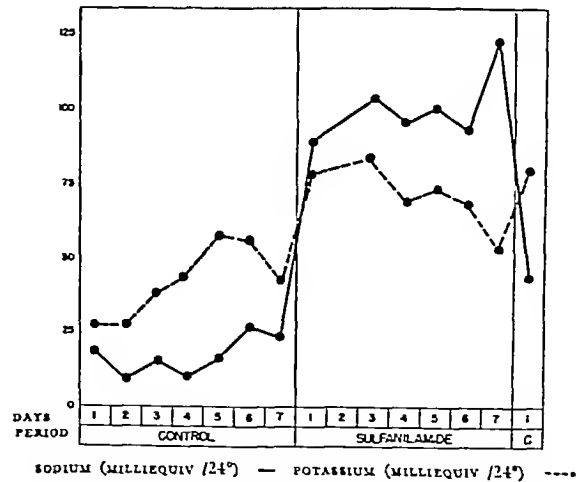

FIGURE 3 Effect of Sulfanilamide on Urinary Sodium and Potassium in Case 3

the patient had a shaking chill and developed a temperature of 105°F. Sulfanilamide was discontinued, and penicillin and streptomycin begun after blood cultures had been taken. During the next 4 days the patient continued to show a spiking fever, with temperature elevations as high as 105°F and remissions to virtually normal temperatures. On the 5th day the temperature returned to normal, and the patient's

Sulfanilamide is unquestionably too toxic a drug for prolonged or routine use in the inhibition of carbonic anhydrase. It should be noted that whereas the amino group in the para position to the sulfonamide group is necessary for the antibacterial activity of sulfanilamide,²⁻⁸ it is not essential for the effect on carbonic anhydrase. It is the free sulfonamide group that is directly concerned with the inhibition of this enzyme.² A number of other sulfonamides with free sulfonamide groups have been shown to have an effect on carbonic anhydrase similar to that of sulfanilamide.²⁻⁹ In addition, Höber¹⁰ has demonstrated that the addition of sulfanilamide and of compounds with an unsubstituted sulfonamide group to the perfusion fluid of an isolated frog kidney changes the reaction of the secretion from acid to alkaline. Compounds of this type are under investigation in an attempt to find one less toxic than sulfanilamide. The evidence available at present does not permit a conclusion about the potential relative merits of this method of diuresis as compared to others now in common use. Studies also have been too short to indicate whether the increased base excretion would continue if carbonic anhydrase inhibition were maintained for a prolonged period in an edematous patient.

SUMMARY

Evidence indicating that sulfanilamide is capable of producing an increased sodium, potassium and water excretion in patients with congestive heart failure is presented. It appears that the inhibition of carbonic anhydrase in the cells of the renal tubules is responsible for this phenomenon. Other sulfonamides that are also inhibitors of carbonic anhydrase are under investigation in an effort to find a compound less toxic than sulfanilamide.

*Specimen lost.

further course was uneventful. During this period there were no signs of increasing heart failure. No cause for the fever was ascertained. There was no evidence of blood stream, urinary-tract or other infection. Whether the fever represented a reaction to sulfanilamide is a matter of conjecture.

DISCUSSION

All patients showed an increase in sodium and potassium excretion within the first twenty-four hours of sulfanilamide administration. The 2 patients in whom it was possible to continue the drug for a seven-day period maintained a high daily output of sodium in the urine, which was four to five times the control value, and exhibited a weight loss that correlated with the increase in sodium output. The urine pH increased in all cases. At the same time there was a sharp fall in carbon dioxide combining power of the serum accompanied by an increase in chloride. These changes can best be explained by an inhibition of carbonic anhydrase in the renal parenchyma with retention of hydrogen ions and concomitant diminution of sodium reabsorption. It was of some interest that the withdrawal of sulfanilamide resulted in a fall in sodium excretion to lower levels than those observed in the pretreatment period ("rebound phenomenon") in the 2 patients observed for a prolonged period.

The inhibition of carbonic anhydrase by sulfonamides was described by Mann and Keilin² in 1940. They demonstrated that only compounds with a free sulfonamide group are inhibitors of carbonic anhydrase. It would not be expected, therefore, that any of the recent sulfonamide compounds that have replaced sulfanilamide in clinical use would be capable of inhibiting carbonic anhydrase since they contain substituted sulfonamide groups.

Studies on acid-base balance in patients receiving sulfanilamide,³⁻⁶ when this drug was the only compound in general clinical use, revealed a pattern that might have been predicted had its action on carbonic anhydrase been known. Subjects were found to show an increase in urine volume and sodium excretion accompanied by an increase in the pH of the urine. At the same time there was a reduction in serum carbon dioxide combining power and pH. Roughton and his co-workers⁷ studied a group of patients receiving 2 to 3 gm of sulfanilamide daily. They found that during rest and moderate exercise (five or six times resting metabolism) the rate of carbon dioxide elimination was not impaired.

There was no response to appropriate treatment instituted on a tentative diagnosis of rheumatic heart disease and mitral stenosis and insufficiency, and death occurred on the 25th hospital day. Before death the face and hands became edematous, and the color of the skin was almost heliotrope. The hemoglobin and red-cell count fell to half the normal values. Anuria developed 48 hours before death, and the urine contained red cells and a few casts. During the last 5 days of life the temperature was elevated to 101°F. The final clinical diagnosis was rheumatic heart disease, mitral stenosis and insufficiency, bacterial endocarditis, cardiac hypertrophy, myocardial fibrosis and terminal nephritis.

At autopsy* the heart weighed 500 gm. The right ventricle, right auricle and pulmonary artery were greatly dilated. The myocardium was flabby. The orifice of the mitral valve was narrowed to a mere slit, and the margins were distorted by soft, friable vegetations (Fig. 3). These vegetations extended along the free surface of the valve to the chordae tendineae, which were thickened and shortened. The foramen ovale, which measured 5 cm in diameter, was not involved. The coronary vessels were patent. The mitral valve measured 10 cm, the aortic valve 7.1 cm, the tricuspid valve 16.0 cm, and the pulmonary valve 9.5 cm. The left ventricle was 11 cm thick. The right ventricle was 0.5 cm thick, and its diameter was 11.5 cm. The pathologist's anatomic and microscopical diagnoses were interauricular septal defect, subacute bacterial endocarditis, healed rheumatic endocarditis, cardiac hypertrophy and dilatation, multiple pulmonary infarcts and focal embolic nephritis.

DISCUSSION

To date the combination of interauricular septal defect and mitral stenosis (Lutembacher's syndrome) seems to have been recorded in combination with bacterial endocarditis in only 3 cases.¹⁻³ The complete report of Geiger and Anderson,³ who made the diagnosis before death in a patient observed for eleven years, makes any extended comment on the case reported in this communication entirely superfluous.

The lesson of the case is obviously the overlooked diagnosis. It was a diagnostic as well as a therapeutic error to eliminate subacute bacterial endocarditis from consideration on the basis of a single negative blood culture; antibiotic therapy should have been instituted on the mere suspicion. The diagnosis of interauricular septal defect was overlooked for the most usual of all reasons—failure to recollect an uncommon though by no means rare condition. Actually, the roentgenologic and fluoroscopic diagnostic criteria were met,⁴ the electrocardiogram was characteristic, and the cardiac findings and ante-mortem lividity (*cyanose tardive*) were also characteristic. Had these observations been evaluated properly and in their entirety, there is every reason to believe that a correct diagnosis could have been made before death.

Another point of interest in this case is the remarkable tolerance shown by the patient to the

difficulties of life. Such tolerance is frequent in patients with congenital interauricular septal defects.⁵

SUMMARY

A case is recorded of interauricular septal defect combined with mitral stenosis (Lutembacher's syndrome) and with bacterial endocarditis. It is

FIGURE 3 Interauricular Septal Defect Associated with Mitral Stenosis and Subacute Bacterial Endocarditis. Note the vegetations extending proximally from the free border of the mitral valve.

apparently the fourth case of this kind to be put on record. Diagnostic considerations are briefly discussed.

LUTEMBACHER'S SYNDROME ASSOCIATED WITH SUBACUTE BACTERIAL ENDOCARDITIS*

Report of a Case

EDWARD R. H. KURZ, M.D.,† AND ISIDORE FISCHER, M.D.‡

WHITE RIVER JUNCTION, VERMONT, AND NEW YORK CITY

THE following case of Lutembacher's syndrome (interauricular septal defect and mitral stenosis) associated with subacute bacterial endocarditis is considered worthy of comment since it appears to be the fourth such case to be recorded in the medical literature.

A forty-seven-year-old man was admitted to the hospital after he had suffered for 2 months from progressively more

Positive cardiac findings included a systolic thrill at the apex, a very short diastolic murmur at the mitral area, a harsh, blowing diastolic murmur in the second and third left interspaces to the left of the sternum, and a loud systolic apical murmur transmitted to the axilla. The fluoroscopic findings consisted of moderate enlargement of the outflow and inflow tracts of the left ventricle, characterized by elongation, horizontal and vertical enlargement of the left auricle, marked enlargement of the outflow tract of the right ventricle, with some enlargement of the inflow tract, marked enlargement in the region of the pulmonary conus, and enlargement of the appendicular portion of the right auricle.

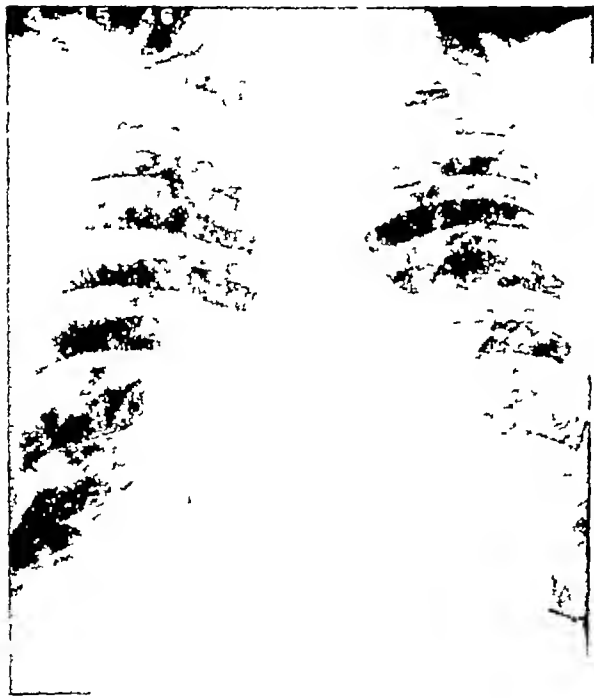

FIGURE 1 Roentgenogram of Chest, Showing Enlarged, Triangular Cardiac Shadow, Prominent Pulmonary Conus, Thickened, Hazy Pulmonary Shadows and Prominent Hilar Shadows

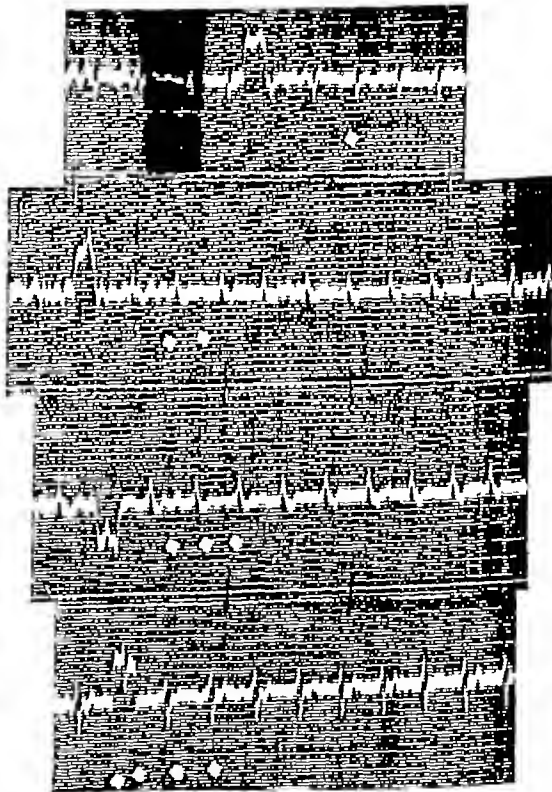

FIGURE 2 Electrocardiogram, Showing Auricular Fibrillation, Marked Right-Axis Deviation, Low-Voltage T Waves and Slurred and Notched QRS Complexes

severe dyspnea, orthopnea and hemoptysis. The past history was entirely irrelevant except for an attack of apparent rheumatic fever 20 years earlier. In the interim he had been in active service in the Royal Canadian Field Artillery and had done work in a woolen mill.

‡Assistant adjunct physician Department of Internal Medicine Bronx Hospital formerly medical officer (ward) Veterans Administration Hospital White River Junction Vermont.

The arch of the aorta appeared normal. A roentgenogram of the chest (Fig. 1) showed cardiac enlargement, prominence of the pulmonary conus, thickened pulmonary shadows and prominent hilar shadows. The chief electrocardiographic finding (Fig. 2) was marked right-axis deviation. Laboratory examinations were within normal range, and a blood culture was sterile.

With few exceptions clinical efficacy can be predicted from antibacterial potency. Table 1 shows the generally accepted clinical indications for each drug, these parallel, on the whole, the growth-inhibiting capacities of the drugs for each species in vitro. There are a few outstanding exceptions, however, which are still unexplained. Clinical *diphtheria* does not respond to treatment with penicillin although levels can be established that are more than adequate for control of the bacillus in vitro. Penicillin as an adjunct to antitoxin and other measures is nevertheless indicated for the prevention of suppurative complications, and the carrier state responds dramatically to the drug.³²⁶ *Typhoid and paratyphoid fevers* are refractory to streptomycin therapy despite sensitivity of the organisms.²⁹³ *Brucellosis* also fails to respond to streptomycin.³²⁷ ³²⁸ recent reports, however, point to a synergism of sulfadiazine and streptomycin,³²⁹ and a small number of acute and chronic cases in human beings have been cured by the combined drugs.³³⁰ ³³¹

It will be observed that the affinities of penicillin and streptomycin do not overlap but that sulfonamides share with either drug their potency against a number of species. When sulfonamides and penicillin are equally effective, the latter is the drug of choice for reasons of comparative toxicity. In meningococcal meningitis penicillin is looked upon with disfavor because of its poor penetration into the normal cerebrospinal fluid, most clinicians favor sulfadiazine,²⁹¹ or sulfadiazine in addition to penicillin. Opinion is divided on the treatment of pneumococcal pneumonia, both drugs are highly effective and in general use. When sulfonamides and streptomycin are equally effective the former are often favored because they are less toxic. Of the many diseases once treated with sulfonamides³³² ³³³ only cholera, chancroid, lymphogranuloma inguinale and trachoma remain uniquely responsive to these drugs, and uninfluenced by either penicillin or streptomycin. Closely related to the sulfonamides are the sulfone drugs, — diasones, promine and promizole, — which are being used with encouraging success in the treatment of leprosy,³³⁴ and other sulfones have a promising tuberculostatic action.³³⁵ ³³⁷ Several general reviews of sulfonamides in clinical practice have appeared.¹⁹⁶ ³³³ ³³⁹

Penicillin Therapy

The remarkable successes achieved with penicillin in streptococcal and staphylococcal infections, especially in subacute bacterial endocarditis,³⁴⁰ in the prophylaxis of streptococcal infection,¹⁸³ in gonorrhea,³⁴¹ ³⁴² in pneumococcal infection, in gas gangrene, in actinomycosis³⁴³ and in a variety of

surgical conditions³⁴⁴ are fully presented by many clinical investigators.

Perhaps the most remarkable consequence of the penicillin era has been the complete revolution brought about in antisyphilitic therapy. Cure rates in primary and secondary syphilis compare favorably with those obtained by the best of the older methods and without the previously attendant risk of grave injury from the therapeutic agent.³⁴⁵ ³⁴⁵ Evaluation of results in treatment of tertiary syphilis requires many years of follow-up study, but it is not unlikely that this outcome will also be favorable.³⁴⁶ The drug is certainly beneficial in cerebrospinal forms of the disease,³⁴⁷ ³⁴⁸ but there is still doubt whether it is as effective as arsenical and fever therapy. Various combined treatments have been advocated, directed especially toward the 5 to 10 per cent of cases that are resistant to repeated courses of penicillin. Thus, oxophenarsine and fever have been used as adjuncts to penicillin, but sufficient data are not yet available for sound evaluation. The work of Moore³⁴⁵ and Pillsbury,³⁴⁹ the authoritative reports of the Syphilis Study Section of the National Research Council³⁵⁰ ³⁵¹ and the recent review by Crawford³⁵² present full details of the efficacy of penicillin in syphilis. Several other more general summaries of the clinical uses of penicillin have appeared.²²⁸ ³³⁹ ³⁵³–³⁵⁷

Streptomycin Therapy

With the exceptions noted above, streptomycin is effective in the clinical treatment of diseases produced by gram-negative bacteria. It has proved dramatically successful in tularemia³⁵³ ³⁵⁹ (particularly the pneumonic form) and in plague.³⁶⁰ It is strikingly curative also in meningitis due to *Haemophilus influenzae*,¹⁷⁹ ³⁶¹ ³⁶² in infection due to *Klebsiella pneumoniae* (Friedländer's bacillus) and in meningitis due to salmonella organisms, despite its inefficacy in enteritis caused by *Salmonella enteritidis*. It has proved useful in the control of dysentery of the *Shigella dysenteriae* form, in relapsing fever due to *Borrelia recurrentis* and in granuloma inguinale,³⁶³ ³⁶⁴ in which it appears to be far superior to the organic antimonials. Its main surgical uses have been in the preoperative sterilization of the bowel³⁶⁵ and in a variety of local infections caused by gram-negative bacilli.³⁶⁶ Its most widespread employment has probably been in the treatment of chronic urinary-tract infections due to *Proteus vulgaris*, *Aerobacter aerogenes* and *Pseudomonas aeruginosa* and other gram-negative species, here results have been good, but relapse is common, resistance develops frequently, and streptomycin cannot replace surgery when an anatomic abnormality is at the root of the infectious process.²²⁵ ³⁶⁷

Full discussion of the advances made in the therapy of tuberculosis with streptomycin is beyond the scope of this review. In brief, the drug has a

*Adoption of the revised nomenclature " Hansen's disease" is advocated by the patients at the Carville Leprosarium.³⁴¹

Binding to Plasma Protein

The experiments of Davis³⁰⁷⁻³¹⁰ and subsequent reports by the same author and others³¹¹⁻³¹² established that sulfonamide action depends upon the level of *unbound* drug in the plasma water. At therapeutic concentrations sulfanilamide is protein bound to an extent of 20 per cent, sulfapyridine 40 per cent, sulfathiazole 75 per cent, sulfadiazine 56 per cent, sulfamerazine 84 per cent, and sulfamethazine 84 per cent^{289, 303, 313, 314}. It should be noted, however, that the usual technics for determining plasma levels do not distinguish between bound and unbound drug. The accepted bacteriostatic thresholds for various organisms also refer to total (bound and unbound) sulfonamide. Consequently for clinical purposes no distinction need be made, the total plasma sulfonamide level is a correct guide to the efficacy of treatment.

On the other hand the binding of penicillins by plasma protein presents some practical problems. This binding increases progressively in the order $X < G < \text{dihydro-F} < K$,^{315, 316} following the generally established principle^{317, 318} that interaction with protein is positively correlated with the length of alkyl side-chains. Biologic assay methods may be distorted by a high degree of binding, thus, the dilution of plasma containing penicillin K results in a reversible dissociation, more unbound penicillin becoming available in the assay than was present in the original plasma. Proper corrections should be made for such effects.³¹⁹

It has been established that the usual order of potency *in vitro* is $K > X > G > F$, whereas *in vivo* the order becomes $X > G > F > K$.³²⁰ The strikingly decreased effectiveness of penicillin K *in vivo* has been attributed to its very appreciable binding to plasma protein (86 to 95 per cent).^{315, 319} It is likely that other factors are also involved since penicillin K is not recovered quantitatively from the urine,³⁸⁸ is apparently destroyed in the plasma^{321, 322} and is inactivated by kidney and liver slices more rapidly than the other penicillins.³²³ On the other hand penicillin X, which is almost as highly bound as G, gives higher and more prolonged blood levels than the latter,³²⁴ and has proved more effective, weight for weight, than any of the other penicillins in the cure of a number of infections.³²⁰

The binding of streptomycin to plasma protein, according to one report,³²⁵ is negligible at therapeutic concentrations.

Most chemotherapeutics are bound reversibly, chiefly to the albumin fraction of the plasma. The relation between the extent of binding and antibacterial potency or toxicity to host tissues is by no means obvious. In the sulfonamide series, sulfadiazine and sulfathiazole, which are bound to the greatest extent, are also the most effective antibacterial agents. In the penicillin series the most highly bound compound is also the least effective *in vivo*. There appears to be no correlation here between affinity for plasma protein and toxicity.

One might surmise, especially from the penicillin findings, that binding to plasma protein is an undesirable feature in a chemotherapeutic. This should not be true, however, unless the concentration of *unbound* drug is thereby reduced below the required level. Theoretically, the protein-drug system is a buffer. At constant protein concentration the *fraction* of a total drug that is bound will be higher at low drug levels and lower at high drug levels. The *amount* of bound drug, however, will increase as the drug level is raised. As a consequence, an appreciable quantity of drug may be held in protein combination, to be released progressively as the drug level falls, the bound drug meanwhile being protected from rapid renal excretion. In this view protein-bound drug would act as a reversible depot, tending to damp abrupt rises and falls of the plasma level curve. Whether such a highly desirable effect will actually occur or whether undesirable reduction of potency (penicillin K) will result must depend upon the specific characteristics (dissociation constant and so forth) of each chemotherapeutic. The practical effects of protein binding upon the dynamic aspects of drug action have not been investigated sufficiently for generalizations to be made. Certain aspects of the problem are discussed by Davis⁶ in a recent review.

CLINICAL APPLICATIONS

The practical value of a chemotherapeutic is determined by many factors, the most important of which are the sensitivity of the pathogenic organisms, the ease of maintaining effective drug levels, the toxicity of the drug and the natural course of the disease.

*From the Department of Pharmacology, Harvard Medical School.
†Associate in pharmacology, Harvard Medical School.

this may occasionally prove disastrous is indicated by a report of bacteremia due to *Esch col* with a preponderant throat culture of the same organism in a penicillin-treated patient,³⁵¹ a case of bacteremia caused by *H influenzae* under similar circumstances,³⁵² bacteremia (*Staphylococcus aureus*) in a patient receiving streptomycin,^{362 352} peritonitis due to a streptomycin-resistant strain of *A aerogenes* in another patient treated with streptomycin³⁶⁵ and similar occurrences.^{352 353} As the problem has not assumed alarming proportions, one must assume that when a specific chemotherapeutic

antibacterial affinities, and others with spectrums that overlap those of the older drugs. New affinities obviously open the way to control of the few bacterial infections still eluding specific therapy. The most important of these are the typhoid infections, tuberculosis, the fungal diseases, diphtheria, brucellosis and, in a different group, the rickettsial and virus diseases. Of equal importance would be the availability of more than a single agent with which to attack a given pathogen. Thus, one could prevent the development of resistance by combined attack, combat resistant organisms once established

‡But drug of choice in meningitis caused by this organism

eradicates certain organisms and allows others to flourish unchecked, the body defenses are usually capable of holding the latter within bounds. The interesting question raised by this curious phenomenon is whether the present chemotherapy is too specific or not specific enough. Would it be preferable to select for elimination a single pathogenic species, or should the chemotherapeutic produce a general reduction of all bacterial forms?

NEW CHEMOTHERAPEUTICS

An increasing number of new chemotherapeutics are becoming available, some with entirely original

or replace a chemotherapeutic to which the patient had become sensitive. Less toxic substitutes for streptomycin would prove especially useful. These, in addition to the usual criteria, are proposed as standards for evaluating new chemotherapeutics.

Para-aminosalicylic Acid (PAS)

In 1941 Bernheim,³⁵⁴ studying the metabolic activity of the tubercle bacillus, showed that salicylates and benzoates increase the oxygen uptake of nongrowing suspensions of a virulent bovine strain. Lehmann³⁵⁵ subsequently demonstrated that this effect is obtained only with pathogenic

marked protective and curative action in tuberculosis in experimental animals³⁶⁸⁻³⁷⁰ In early progressive, infiltrating pulmonary tuberculosis in man, it is of decided benefit³⁷⁰⁻³⁷¹ Dramatic cures have resulted from its employment in the miliary and meningeal forms of the disease,³³⁷ and in various types of localized tuberculous infection that are readily accessible to the drug³⁷² In chronic caseating pulmonary tuberculosis it is generally ineffective and therefore probably contraindicated because of the risk of toxicity in prolonged administration Results of treatment of 2780 cases are reported

the treatment of many gram-negative infections, particularly of the urinary tract An early attempt to treat typhoid fever with this drug is on record³¹ The dosage employed was less than 2 gm (2,500,000 units) daily, and yet the clinical responses were encouraging Welch and Randall⁶⁹ subsequently established the bacteriostatic threshold for *Eberthella typhosa* at 3.6 to 7.2 microgm (6-12 units) per cubic centimeter It has not been until recently that unlimited supplies of the drug became available, and meanwhile streptomycin had come onto the horizon as the drug of choice for the gram-nega-

by a Committee of the National Research Council³⁷³ Several general reviews on the clinical use of streptomycin have become available in the past few years⁴⁻³²⁷⁻³²⁸⁻³²⁹⁻³⁷⁴⁻³⁷⁵

The work of Pratt and Dufrenoy,⁸¹ discussed in a previous section, indicated that the action of penicillin is qualitatively similar upon all organisms, except that much higher concentrations are required to inhibit the growth of gram-negative species Indeed most organisms are sensitive to penicillin at some concentration, and the drug is so nontoxic that extraordinarily high levels can be safely maintained in a patient's plasma, and even higher levels in his urine One wonders whether penicillin in "massive" doses might not replace streptomycin in

tive bacteria If one is now willing to use penicillin in the same dosage as streptomycin* a number of pathogens heretofore considered "insensitive" may be found responsive to the less toxic drug

"Superinfection"

A disturbing feature of the clinical use of the chemotherapeutics is the possibility of upsetting normal antibiotic relations between various bacterial species in vivo It is reported, for example, that prolonged treatment with penicillin results consistently in a shift of the bacterial flora of the nasopharynx in favor of the gram-negative species that can flourish in the presence of the drug³⁸⁰ That

*Two grams daily would represent about 3,000,000 units.

fections (chiefly ulcers, carbuncles and chronic osteomyelitis) responded favorably and those due to streptococci and staphylococci, even when these organisms were penicillin resistant, healed dramatically. Further favorable experiences in the local use of the drug are reported by Miller and his collaborators.⁴¹⁴ In neither investigation was toxicity of any kind observed.

Bacitracin has been administered systemically to over 150 patients with a variety of diseases caused by gram-positive organisms, which had failed to respond to sulfonamides or penicillin.⁴¹⁵ In 105 of these cases,⁴¹⁶ the over-all favorable response was about 70 per cent with dramatic cures in some of the streptococcal and staphylococcal infections. Over 100 cases of syphilis have been treated with bacitracin alone or in combination with penicillin,⁴¹⁵ a synergistic effect of the two drugs having been noted in rabbit infection.⁴¹⁷ It is still too early for proper evaluation of these results.

Transient albuminuria and other signs of nephrotoxicity have been observed.⁴¹⁵ These, as was earlier found in animal experiments, vary with different lots of the drug and different production processes. It can be hoped, on the basis of experience with streptomycin, that they will disappear with purification.

The reports cited are promising. The near identity of the antibacterial spectrum of bacitracin with that of penicillin places it at a disadvantage from the standpoint of further development, since it must presumably offer some obvious advantage over the latter. This it may well do in its superior qualities of absorption and excretion, leading to prolonged blood levels, and permitting infrequent injection. Another important advantage is its effectiveness against penicillin-resistant organisms, particularly those which produce penicillinase and thereby nullify the usefulness of penicillin in mixed infections where they are present.

Polymyxin

Polymyxin, isolated by Stansly and his co-workers⁴¹⁸⁻⁴¹⁹ from the soil organism, *B. polymyxa*,⁴²⁰ is a cyclic polypeptide containing d-leucine, l-threonine, d-serine, diaminobutyric acid and a C₂ diamino acid.^{41, 421} It displays greatest specificity toward organisms of the gram-negative group, resembling streptomycin in this respect. Noteworthy exceptions are the insensitivity of *Pr. vulgaris* and the neisseria group. The drug is tolerated by animals and man in bactericidal concentrations. Development of resistance has not yet been observed despite attempts to elicit it in vitro — a fact of outstanding importance if borne out by further experience. The chemotherapeutic ratio, determined in mice and dogs by acute and chronic administration, is highly favorable. The intravenous LD₅₀ in dogs is 25 mg per kilogram of body weight, whereas a single intramuscular dose of 5

mg per kilogram produces effective blood levels for several hours.⁴²² Mice are reported to be protected against infection with *K. pneumoniae* and *H. influenzae*.

Systemic administration of polymyxin to 26 patients has recently been reported.⁴²³⁻⁴²⁴ The drug was given intramuscularly in divided doses totaling 0.2 to 0.5 gm daily, usually about 3 mg per kilogram of body weight a day. Plasma levels of 0.6 to 1.3 microgm per cubic centimeter in twelve hours rise gradually to between 2.5 and 5.0 microgm per cubic centimeter after five or ten days of treatment. The drug does not appear in the cerebrospinal fluid, even in meningitis, but can be administered intrathecally. Excretion in the urine is delayed, but at the end of four days about 60 per cent can be recovered. The infections treated included those due to *Ps. aeruginosa*, *A. aerogenes*, brucellas, *K. pneumoniae* and *E. typhosa*. In all these infections some dramatic cures were observed, especially in cases that had been refractory to all other chemotherapeutics. Five cases of pertussis were also treated. The series is too small for statistical evaluation, but it was the impression of the investigators that some of the responses were unquestionably produced by polymyxin.

Serious nephrotoxic effects have been observed. These occur fairly regularly at the higher dosages and consist of albuminuria, granular casts and occasionally azotemia and diminution of the urine specific gravity. The effects may be very transient, disappearing while the drug is continued, or so severe as to necessitate interruption of therapy. As with bacitracin, production methods have a great deal to do with the toxicity observed. The material used for the studies cited above is about 70 per cent pure, and is designated polymyxin D. British workers have employed a material called aerosporin,⁴²⁵⁻⁴²⁷ which is now referred to as polymyxin A. A new product, which does not contain d-serine, is known as polymyxin B, and its toxicity is presently being investigated, the d-amino acid having been observed to be highly nephrotoxic. Minor toxic reactions to polymyxin include drug fever, anorexia and epigastric distress, and eosinophilia in a single patient. No blood dyscrasias, liver disturbances or skin rashes have been noted.⁴²⁸

Chloromycetin

Early this year Ehrlich and his collaborators,⁴²⁹ and simultaneously Gottlieb and his co-workers,⁴³⁰ reported the isolation, from a species of streptomycetes, of a new antibacterial compound containing nonionic chlorine. This substance, named "chloromycetin," has several remarkable properties — an effective oral absorption, unusually low toxicity, high activity against many gram-negative organisms, proved antirickettsial activity under laboratory conditions and early clinical results that are highly promising.⁴³¹

organisms, whether human or bovine. It appeared highly probable that these compounds were being utilized as substrates for respiration, and the effect of a series of structural analogues was investigated. Para-aminosalicylic acid (PAS) was shown to inhibit growth of *Mycobacterium tuberculosis* in vitro at a concentration of $10^{-5}M$. Blood levels of this order could be established by oral administration to animals and man. Lehmann³⁸⁶ reported the treatment of 20 tuberculous patients with doses of 10 to 15 gm daily, giving blood levels of 2 to 7 mg per 100 cc.

Youmans and his associates^{387, 388} confirmed the bacteriostatic effect of PAS at 0.01 to 0.1 mg per 100 cc in vitro but found the toxic dose in mice to be extremely close to that required for effective blood levels. Strains that were sensitive and those that were resistant to streptomycin were equally inhibited. Although survival of treated infected mice was significantly prolonged, all the animals showed tuberculous lesions at autopsy. Very similar results were obtained in rabbits and guinea pigs by McClosky and his co-workers,^{389, 390} who also found mere summation of effects when PAS and streptomycin were combined. On the other hand Vennesland et al³⁹¹ showed striking enhancement by PAS of the bacteriostatic action of streptomycin in vitro.

Feldman and his associates³⁹² obtained impressive cures in guinea pigs when treatment was started six weeks after infection. Although 4 per cent PAS was included in the diet, no toxicity was observed. However, the low blood levels (0.5 mg per 100 cc) suggest that not all the drug was actually ingested and absorbed.

It appears to be the general consensus that PAS is much less effective than streptomycin. However, further clinical trials are under way, and it is conceivable that the drug may be a useful adjuvant to therapy with more potent chemotherapeutics. It would be interesting to explore the possibility of employing PAS during rest periods punctuating an intermittent course of streptomycin.

Subtilin, Subtenolin and Bacillomycin

After Dubos had isolated tyrothricin from *Bacillus brevis*, several groups of investigators turned to *B. subtilis*, another gram-positive spore-forming organism, as a possible source of chemotherapeutic material. Employing Dubos's procedure, Jansen and Hirschmann³⁹³ isolated *subtilin*, a polypeptide that, in contrast to tyrothricin, is rapidly diffusible and considerably more toxic to bacteria than to tissues.³⁹⁴ Its antibacterial spectrum includes the common gram-positive species (streptococci are very sensitive), *M. tuberculosis* and certain pathogenic actinomycetes.^{395, 396} Mouse pneumococcal and streptococcal infection was aborted as late as nine hours after inoculation,^{397, 398} but the experiment reported is inconclusive since both infecting organisms and drug were injected

into the same site (intraperitoneal). The drug also displays affinity for treponemas in vitro but is less effective than penicillin on a weight basis, and even large doses fail to heal the primary chancre of rabbit syphilis.³⁹⁹ Although four years have elapsed since its isolation, no clinical reports on subtilin have appeared, nor are complete animal toxicity studies available.

A surprising number of different compounds have been obtained from *B. subtilis*, all of which show growth-inhibiting activity against micro-organisms in vitro. Only the most promising of these can be mentioned here; a more complete discussion is found in a recent review.⁴⁰⁰ *Subtenolin* is an enolic compound of low molecular weight, active against streptococci and staphylococci and a large group of gram-negative species including *E. typhosa*, *Esch. coli*, salmonella and pasteurella.⁴⁰¹ Mouse-toxicity studies are encouraging, but the drug is still impure and in the early stages of investigation.⁴⁰² *Bacillomycin* is of interest because it is almost devoid of antibacterial action and yet highly toxic for most pathogenic fungi.⁴⁰³

Bacitracin

Bacitracin, also isolated from *B. subtilis*, is a diffusible polypeptide of low molecular weight whose composition differs in two or more amino-acids from that of subtilin.⁴⁰⁴⁻⁴⁰⁶ It resembles penicillin in its activity toward a variety of gram-positive bacteria and spirochetes. Eagle^{399, 407} has shown that the spirocheticidal action differs from that of penicillin and resembles that of the disinfectants in that the rate of killing is proportional to concentration up to the highest levels tested. In rabbits doses far below the toxic suffice to abort syphilitic infection and heal primary lesions. Gravimetrically, it is stated, the drug is less potent than penicillin, but this comparison, as pointed out above, is irrelevant except in relation to the toxicity of each compound. Bacitracin is excreted by glomerular filtration and more slowly absorbed from parenteral sites than penicillin so that its pharmacodynamic properties are highly favorable.⁴⁰⁸ In the dog effective levels persist in the blood for five to ten hours after intramuscular injection of 3000 to 6000 units per kilogram of body weight, a dosage at which no toxic effects are observed.^{409, 410} In mice and rats large doses produced renal lesions (in the former) and convulsions leading to death, but as these effects were not correlated with the antibacterial potency of different lots it seems likely that they were caused by an impurity.⁴¹¹ Like penicillin, the drug is not well absorbed by the oral route, but it is not inactivated in the gastrointestinal tract, retaining activity against susceptible enteric pathogens.⁴¹²

Meleney and Johnson⁴¹³ report favorably upon 100 cases of surgical infection treated topically with solutions or ointments containing 10 to 100 units per cubic centimeter. About 88 per cent of the in-

can be made against a great many such infections despite the lack of an obvious rationale. It is curiously typical of the history of chemotherapy that fundamental understanding of the underlying principles has often lagged behind their practical employment in the treatment of infectious disease.

* * *

The recent prodigious advances in antibacterial chemotherapy, whose highlights have been reviewed here, exert a profound influence upon all the biological sciences and upon the practice of medicine. They offer sure promise of a day when harmless drugs of precise specificity will endow the clinician with the power to destroy every pathogen that threatens the life or health of man. To the laboratory investigator, in whatever field he works, the chemotherapeutic drugs are delicately fashioned tools for probing the intimate mechanisms of the life process. By their very nature they lay open the living cell, exposing the complex metabolic patterns upon which *all drugs* must act. This deeper significance of chemotherapy to the whole of pharmacology was never more clearly discerned than by Ehrlich² himself, when he wrote

I am of the opinion that the fundamental question of pharmacology, the question of the combination of drugs and the cause of such combination, will hardly be brought to a solution in the complicated system of the higher organism, rather is it more to the point to study such processes in their purest cellular form, in the simplest of cells

The antibacterial spectrum of chloromycetin is qualitatively similar to that of streptomycin, although it has low potency against the tubercle bacillus in proportion to its activity against the common pathogens. Parenteral injection in dogs produces local tissue necrosis and certain untoward systemic effects, but this mode of administration is rendered unnecessary by the efficient absorption of the drug from the gastrointestinal tract. Levels higher than 10 microgm per cubic centimeter are easily achieved in dogs and man by ingestion of a 1-gm dose. Larger amounts are tolerated, but rapid absorption and excretion make for familiar difficulties in maintaining constant plasma levels. However, the need for very frequent dosage is not a serious drawback in oral medication. Chloromycetin is about 60 per cent bound to plasma protein at therapeutic concentrations.^{432 433}

Mouse protection and therapy are achieved in a variety of infections. Tuberculosis in the guinea pig could not be controlled, failure to reach effective blood levels (12.5 microgm per cubic centimeter) apparently accounting for the unfavorable results.⁴³⁴ Its antirickettsial action is perhaps the drug's most striking feature. The life of chick embryos infected with the agents of typhus and scrub typhus was unquestionably prolonged, in one experiment, although all controls died eight days after infection, eight of twenty-four embryos hatched on the fifteenth day.⁴³⁵ Doses of 50 to 100 mg per kilogram of body weight clear the lesions of rabbit syphilis, but only temporarily.⁴³² However, it is not stated whether this was the maximum tolerated dose.

Organisms sensitive in vitro to less than one microgm per cubic centimeter include *Borrelia recurrentis* (0.00625 microgm per cubic centimeter), brucella, *E. typhosa*, *Esch. coli*, *H. pertussis*, *K. pneumoniae*, pasteurella, salmonella, shigella, *Pr. vulgaris*, streptococcus and staphylococcus.^{430 432}

The unusual antirickettsial activity led to early clinical trial in scrub typhus. Preliminary data on 5 patients⁴³⁶ were unconvincing, but subsequent reports of 25 treated and 12 untreated patients show an impressive reduction in the duration of fever, and an average shortening of hospital stay from thirty to nineteen days.⁴³⁷ As against 2 complications and 1 death in the control group, no complications or fatal cases occurred in the treated group. The dosage employed was 50 mg per kilogram of body weight initially and 200 to 300 mg every two to four hours thereafter to a total dose of about 6 gm. All medication was by mouth.

Equally impressive were the first results obtained in typhoid fever which is notably resistant to other chemotherapeutics. Woodward and his collaborators⁴³⁸ report 10 cases with positive blood culture treated with 19 gm over a period of eight days. On this regime (50 mg per kilogram of body weight initially) blood levels of 40 to 80 microgm per cubic centimeter in the first day fell to a plateau of about

20 microgm per cubic centimeter, which is eighty times the inhibiting level for *E. typhosa* in vitro. Response in all patients was prompt, blood cultures becoming negative and fever subsiding promptly. Treatment was started on the ninth day of the disease, after which the patients treated became afebrile in a mean period of three and a half days, whereas the corresponding period in 8 controls was twenty-six days. However, 2 of the 10 patients treated developed perforation or hemorrhage during the afebrile period.

Aureomycin

In very recent months reports of a new and unusual substance have begun to appear. Isolated by Duggar from a streptomyces species it is named "aureomycin," because of its yellow color. The work dealing in detail with the antibacterial spectrum of this compound and its toxicity in animal experiments^{439 440} is not yet in print at this writing. Aureomycin is said to be effective against streptococci and staphylococci, *Diplococcus pneumoniae* and several gram-negative species including *A. aerogenes*, *K. pneumoniae*, *H. influenzae* and the brucella group.⁴⁴¹ In this respect the drug resembles streptomycin. Unlike the latter, it also displays marked antirickettsial action and, uniquely, is also effective against certain virus infections.⁴⁴²

Aureomycin has been used locally in 0.5 per cent solution for the treatment of a variety of ocular infections.⁴⁴³ In the opinion of the investigators, it was at least as effective as penicillin in the cure of staphylococcal conjunctivitis, and was also strikingly curative in a number of conditions known or presumed to be viral in origin. No irritation or other toxic effects were observed.

Excellent response is reported in a small series of patients treated systemically with aureomycin.^{441 444} These include cases of brucellosis, typhoid fever, urinary-tract infections caused by the coli-aerogenes group and *S. faecalis*, and other bacterial infections. The most remarkable results⁴⁴⁵ were obtained in Rocky Mountain spotted fever (14 cases), typhus (Brill's disease) and scrofula.

The antiviral properties of the new drug were demonstrated⁴⁴² by an impressive protection of mice infected intracerebrally with lymphogranuloma inguinale. In 25 patients with this disease, treated by the daily intramuscular injection of 10 to 40 mg of aureomycin, improvement was seen in all. In 8 patients with buboes, there was a definite reduction in bubo size after four days of therapy and a parallel disappearance of elementary bodies from tissue cells. Similarly encouraging results were obtained in cases with proctitis and rectal stricture. These results were obtained despite the absence of a detectable aureomycin level in the blood.

The proved efficacy of chloromycetin in rickettsial and of aureomycin in both rickettsial and virus disease leads one to hope that real inroads

CASE 35051

PRESENTATION OF CASE

A fifty-three-year-old woman was admitted to the hospital because of nausea, vomiting and abdominal pain.

Ten years before admission, eight hours after a lobster dinner, she suffered an attack of "acute indigestion" with sudden, sharp pain in the epigastrium, nausea and vomiting, she recovered by the next day. Eight years before admission she had a similar attack following another lobster meal. Five years before admission she had dull, epigastric pain with nausea and vomiting after an evening meal at which cantaloupe had been one of the items on the menu. Two months before admission she had a short, similar attack following corn on the cob. Thirty-six hours before admission, following breakfast of orange juice and coffee, she noted dull, left, epigastric pain, which soon moved to the right side. She became nauseated and vomited the breakfast. The pain spread toward the umbilicus and was "like something wanting to get through but couldn't." She continued to vomit whenever she took any water. At noon an enema was productive of large amounts of brown feces. She continued to vomit in the afternoon and evening whenever she took liquids. The next day she was able to retain tea and water. The dull pain around the umbilicus persisted. She had no bowel movements and passed no gas by rectum. There was no vomiting, but she did feel nauseated. No history of chills, fever or jaundice was obtained.

On physical examination the chest was clear. The patient was quite comfortable when lying in bed, except when she moved, and then there was pain around the umbilicus. The abdomen was tense and distended, and there was periumbilical tenderness. The peristaltic sounds were low-pitched and active. No masses were palpable. Vaginal and rectal examinations were negative.

The temperature, pulse and respirations were normal. The blood pressure was 110 systolic, 70 diastolic.

Examination of the blood showed a hemoglobin of 14 gm and a white-cell count of 21,000, with

86 per cent neutrophils. The platelets appeared to be increased in number. The urine showed a +++ test for albumin and a few hyaline casts in the sediment.

On the evening of the day after admission the rectal temperature was 101°F, and the pulse 120. There had been no change in the type of pain. The patient had retained all fluids taken during the day. There had been no bowel movements since admission, nor had any gas been passed. The abdomen was more distended, and there was slight bluish-red periumbilical discoloration. The abdomen was tympanitic. There were no peristaltic sounds, and only a few high-pitched, metallic tinkles were heard. On the third hospital day the temperature had returned to normal. The patient ate some food and vomited bile several times. The abdomen was less tense since an enema was given with the return of a small amount of feces.

Another urine examination revealed a + test for albumin. The white-cell count was 9800, with 90 per cent neutrophils. The serum nonprotein nitrogen was 42 mg, and the total protein 5.7 gm per 100 cc. The van den Bergh test was 0.5 mg per 100 cc direct and 0.8 mg per 100 cc total. The amylase was 70 units, the prothrombin time was 22 seconds (normal, 16 seconds). The chloride was 88 milliequiv per liter.

X-ray studies were reported as follows:

The gall bladder concentrates the opaque dye moderately well. There are two nonopaque stones, 8 mm in diameter, in the gall bladder. Barium filling of the large bowel demonstrates a narrowing in the sigmoid, 8 cm in length, which is persistent as long as the patient is in the supine position. In this position there is a suggestion of extrinsic pressure on this portion of the sigmoid from the right and from behind. With the patient in the prone position, however, this loop can be made to distend to practically normal caliber. The mucosal pattern of the sigmoid appears to be intact. Just distal to the hepatic flexure there is a second area of narrowing. Here again the mucosa appears to be intact, and the bowel can be displaced by turning the patient into the prone position. The bowel is displaced somewhat inferiorly, apparently by a mass extrinsic to the bowel.

On the fourth day the patient complained of pain over the left lower ribs anteriorly on breathing. A chest x-ray film showed an area of increased density above the left leaf of the diaphragm that was consistent with an infarct. Homans's sign was negative. Dicumarol was started at this point. The next day she appeared improved. Gas was being passed by rectum, the abdomen was softer, and peristalsis was active. The prothrombin time was 17 seconds (normal, 16 seconds), the serum amylase was 34 units. The stool was guaiac negative and bile positive. An intravenous pvelogram was negative.

On the seventh day the temperature rose to 102°F (rectal). There was moderate distention, and a mass, 6 by 4 cm, was present in the right upper quadrant. The mass was firm and nontender, not attached to the gall bladder and had a limited

in both liver function and pancreatic function. This would have been due to acute pancreatitis and acute cholangitis of brief duration. At least the anatomic basis for that was shown to exist. Some changes in the filling of the large bowel were also observed, and in the examination of the small bowel later on we find the report of what seemed to be extrinsic lumps in the abdomen. Whether these lumps were tumor or whether they were swollen areas resulting from the pancreatitis of fat necrosis and reaction in the mesentery and omentum cannot be told by this sort of x-ray study. All we know is that the bowel seemed to be displaced and the liver distorted by extrinsic masses scattered through the abdomen.

The final complication on the fourth hospital day seems to have been pulmonary embolism, with a small infarct, six days after the illness began. However, she was getting better, and in time more tests and procedures like intravenous pyelograms were possible and the serum amylase had fallen within normal range and the prothrombin time was better. I do not suppose she was given vitamin K or transfusions?

DR SIMEONE: She was not given vitamin K.

DR DOCK: This might be a daily variation in the prothrombin level in our laboratory. I am sure that at this hospital nothing like that could happen. This does represent improvement in the function of the liver. The temperature rose, and again there were signs of distention and paralytic ileus. At this time a mass was felt in the right upper quadrant, which had not been felt before. I take it that at the beginning of the illness the abdomen was difficult to palpate, but the mass was now easy to palpate. This makes it seem much more probable that it was the development of a cyst or some other reaction to pancreatitis than a tumor deeply buried and in a few days coming to the surface. The duodenum was now displaced medially and anteriorly—the second portion medially. One would not expect that something developing around the pancreas in the retroperitoneal tissues would push the duodenum medially. It is surprising. If we did not have the intravenous pyelogram, we would think more of a lesion of the right kidney as the cause of the displacement of the duodenum in the direction indicated. That seems unlikely here.

We come to the further observation of something outside the small bowel, and outside the large bowel, which looked like tumor masses in the mesentery and omentum or local areas of inflammatory reaction and edema, perhaps associated with fat necrosis, if pancreatitis was actually the cause of the trouble. She slowly but steadily got better, but the masses became more and more easily felt and were sharply defined as the illness went on. Again I have to ask if a lipase of 18 units is significant.

DR SIMEONE: It is considered normal.

DR DOCK: Both lipase and amylase determinations were normal at this time. The total protein came down from 5.7 to 4.3 gm per 100 cc, which might indicate that the patient had a good bit of parenchymal liver damage, and which could again have been the result of pancreatitis. At no time was a palpable liver observed, and never any tenderness where the liver margin might be. One might be concerned about the woman's having already had liver disease, ordinary Laennec type, which would lower her prothrombin time and total protein. She had retention of bromsulfalein of significant degree, evidence of liver dysfunction without a palpable liver, which I should expect if the liver damage were recent. The renal function was all right. In general, the patient improved but continued to have fever, which we see in some cirrhotic patients and those with pancreatitis. The patient died suddenly. Since she had had a previous pulmonary infarct, the ordinary supposition would be that this woman in the fourth week in the hospital had died of pulmonary embolism—not an uncommon possibility in a patient with a history like this.

So putting all these things together my own impression is that this woman had acute pancreatitis followed by cyst formation in the neighborhood of the pancreas and perhaps by the development of masses in the omentum and mesentery from fat necrosis. Perhaps also she had Laennec's cirrhosis. Nothing is said about an alcoholic background. I do not know whether or not some of the injury was due to alcohol. I think there is more pancreatitis in patients with cirrhosis than one would get with chance occurrence of the two disorders. So that is not an extraordinary combination of diagnoses. If she had cirrhosis, it is not surprising to have superimposed a recent acute pancreatitis. Those are the diagnoses that I would have made had I seen the patient, and I would have been much less impressed by the possibility of all these being due to cancer with tumor masses in the abdomen. I think it is very unlikely that this was due to a combination of vascular accidents, such as diffuse arteritis. Diffuse arteritis can produce pancreatitis and hepatitis. It can produce acute attacks of bowel obstruction due to interference with the arterial supply to the intestine, with paralytic ileus. So while the possibility exists, it seems to me it is more likely that she had acute pancreatitis, associated with either cirrhosis or chronic gall-bladder disease, that was apparently smoldering along when she died of pulmonary embolism.

DR TRACY B. MALLORY: Is there anything of interest in the x-ray films?

DR STANLEY M. WYMAN: We have a large number of x-ray films, but I really think they are quite confusing. If you would like to see them—

range of motion There was no fluid wave The blood sodium was 130 milliequiv, and the chloride 87 milliequiv per liter A gastric series was reported as follows

The second portion of the duodenum is displaced medially and anteriorly There is rather marked dilatation of the proximal jejunum, with irregularities and coarsening of the mucosal pattern The ileum similarly shows abnormality in pattern, with considerable segmentation of the barium column The small intestine appears ovoid in the left lower and right upper abdomen, as though it might be displaced by masses in these regions

By the fifteenth hospital day the patient had slowly improved The mass in the right side of the abdomen was better defined and not tender There had been some slight diarrhea The serum amylase was 27 units, and the serum lipase was 188 units, the sodium was 130.3 milliequiv and the chloride 88 milliequiv per liter The total protein was 4.3 gm per 100 cc The prothrombin time was 36 seconds (normal, 16 seconds) A bromsulfalein test showed 32 per cent of dye retained in the serum (5 mg per kilogram of body weight) The nonprotein nitrogen was 17 mg per 100 cc, the cephalin flocculation test was + in twenty-four hours, and ++ in forty-eight hours By the twenty-fifth hospital day the mass in the right middle abdomen had become much more clearly demarcated The temperature, which had again returned to normal, was now spiking to 102°F On the evening of the twenty-sixth hospital day she was found pulseless and apneic twenty minutes after having been quite well when she had taken her evening nourishment

DIFFERENTIAL DIAGNOSIS

DR WILLIAM DOCK* This is a history of food idiosyncrasy, characterized by acute attacks The trouble was with lobster, melon and corn on the cob, but not knowing how often the patient was exposed to such food, I cannot attach much significance to these complaints If this were the only occasion on which she ate the food and it produced the illness, it would be clear cut It may have been an accidental relation in her mind between illness and the food she was exposed to

The attack thirty-six hours before admission sounds as if the patient had paralytic ileus or acute bowel obstruction Up to this point a number of things might have been thought about This attack might have been due to coronary occlusion, which often produces abdominal rather than chest pain When the patient is found to be distended and the story of obstruction is as marked as this, that is unlikely The question is whether it was paralytic ileus due to appendicitis or some inflammatory condition in the abdomen or obstruction due to adhesions or to tumor or even to volvulus or something of that sort An interesting thing is that she had a normal pulse, temperature and respirations

at that time, which is surprising because one would think that she might have had shock after thirty-six hours of nausea and vomiting and that the pulse would have been fast Usually, if the patient is in this state, even if peritoneal inflammation has developed, the temperature may be low or normal because of shock, but she had no evidence of shock or of fever The hemoglobin was normal, but she had a leukocytosis She also had polyuria However, the temperature eventually did rise, and the pulse went up to 120, so that one can regard this as a febrile illness She has been hydrated and then showed fever and a fast pulse, which can occur with bowel obstruction or an inflammatory lesion In women past fifty, one thinks of such things as gall stone in the small bowel But usually this picture is produced either by adhesions or inflammation, and the commonest cause is appendicitis, less commonly acute empyema of the gall bladder or acute pancreatitis

The patient was not explored, she was merely kept under observation She had evidence of bluish discoloration, which makes one think that the lesion was somewhere around the liver, it was at the level of the umbilicus, and there may have been some hemorrhage there The subsequent course shows that the discoloration did not increase as a bruise might in making its way to the surface We hear no more about it, and we do not know what it means The signs were those of paralytic ileus, with an inflammatory lesion as the cause, and obviously the surgeons did not believe this was appendicitis or some other disease requiring prompt exploration and drainage The patient improved, the obstruction of ileus cleared, and the white-cell count fell The amylase was 70 units One never knows about the amylase It came down later to 27 units, which I take to be normal

DR F A SIMEONE Thirty-five is the upper limit of normal here

DR DOCK Across town it is 50 units, but an amylase level of 70 units is twice the limit of normal here The patient probably had recent trouble in the pancreas Also, the prothrombin time was longer than it should have been, with a fairly normal serum van den Bergh There was evidence of liver disease with some evidence of change in the liver function, with low prothrombin and elevated amylase In a patient with signs of pancreatitis and an elevated amylase, the problem is whether this is simply acute edema or hemorrhagic pancreatitis, or whether it is a complication of carcinoma of the pancreas What about pancreatitis superimposed upon duct obstruction? The patient apparently was quite well because a Graham test could be performed, revealing that the gall bladder functioned well and showed two stones Thus, it is possible for her to have had an episode in which a stone stuck in the ampulla of Vater It might have caused transient disturbance

*Professor of medicine Long Island College of Medicine Brooklyn New York

abscess and extending into the left gutter secondarily

DR DOCK Perhaps she had a retrocecal appendix

DR SIMEONE It was not visualized by x-ray study. The pain began as described — epigastric distress that moved down about the umbilicus, and we then believed that it became shifting pain. Shifting pain is one of the most characteristic things about acute appendicitis so that when the abscess or the mass began to develop we thought seriously of a ruptured retrocecal appendix.

DR DOCK The bluish discoloration around the navel did not sound as important on the wards as on the chart?

DR SIMEONE No, it was not at all striking. The abdomen was never tender. The only tenderness was in the left flank. The tenderness appeared to be in the wall rather than within the abdomen. We were never impressed with the intestinal obstruction. She did not show gas-filled intestinal loops at any examination, but she did have distention.

CLINICAL DIAGNOSES

Intra-abdominal abscess

Pulmonary embolism

DR DOCK'S DIAGNOSES

Acute pancreatitis, with secondary inflammatory masses or cysts

Possible liver cirrhosis or common-duct stone as predisposing cause of pancreatitis

Gallstones (x-ray diagnosis)

Pulmonary embolism

ANATOMICAL DIAGNOSES

Acute pancreatitis, with retroperitoneal abscess formation

Peritonitis of lesser peritoneal cavity

Cholelithiasis

PATHOLOGICAL DISCUSSION

DR MALLORY Post-mortem examination was limited to the abdomen so I cannot give the cause of the sudden episode, although there is very little doubt that it was pulmonary embolism. In the abdomen we found that the lesser peritoneal sac was filled with turbid fluid, and its wall lined with chalky areas of fat necrosis. There were also large retroperitoneal abscesses running down both gutters close to the spine on each side. These also showed multiple areas of fat necrosis. The pancreas lay in the midst of and between these abscesses. The pancreatic duct was patent, it opened into the duodenum from a separate opening in the papilla of Vater. It could not have been occluded by the passage of gallstones. The common duct was not dilated and contained no stones. There were, of course, a few stones in the gall bladder. Our diagnosis was abscess formation secondary to pancreatitis in spite

of the fact that we found so very little involvement of the pancreas itself. The pancreas did show foci of old fibrosis, suggesting a previous episode of pancreatitis.

DR DOCK The appendix was normal?

DR MALLORY Yes. The culture from the retroperitoneal abscess showed a mixture of colon bacilli and staphylococcus, but the fluid in the abscesses was not foul, and we thought it was terminal infection rather than a primary infectious abscess.

DR WYMAN The head of the pancreas was not enlarged?

DR MALLORY No.

A PHYSICIAN What did the liver show?

DR MALLORY Slight parenchymal degeneration — the type called "cloudy swelling." There were minor degenerative changes in the kidneys as well. In acute pancreatitis one sometimes gets quite severe degenerative changes in both liver and kidneys, but they were not present here.

DR SIMEONE We had another patient — a woman who died about a year ago — with the same disease, who formed similar retroperitoneal abscesses at one of her operations. In the case under discussion at operation we scraped out, from one of the abscesses, putty-like material that looked like necrotic pancreas, and I was amazed at post-mortem examination to find that the pancreas was for the most part normal.

DR DOCK This peripancreatic fat necrosis is not rare in patients who die of involvement of the liver. One finds it microscopically very frequently.

DR MALLORY Sometimes the dissection in these cases is extensive. One patient came to the hospital presenting a scrotal abscess, which was eventually traced up through the retroperitoneal space to the pancreas.

DR DOCK Was the bowel noticeably displaced at autopsy?

DR MALLORY Yes.

DR DOCK Did this patient have antibiotic therapy?

DR JOHN T. QUINBY Yes. She was treated with large doses of penicillin and streptomycin in divided doses.

CASE 35052

PRESENTATION OF CASE

A forty-eight-year-old man was well until three months before admission, at which time he developed moderately severe joint pains in the arches of both feet, both knees, the left hip and both elbows. These symptoms were not relieved by salicylates or vitamin therapy. Two months before admission he developed cough, weakness and weight loss. One month before admission he was hospitalized elsewhere. He was not able to eat

this is a plain film of the abdomen. It shows the two opaque stones described. There is a peculiar gas pattern in the right lower abdomen, but nothing more specific that one can see. The spot film from the pyelogram shows normal-appearing kidneys and upper urinary passages, with no evidence of embarrassment but some pressure on the ureter.

DR DICK: The psoas shadow is very good. One does not see it often in pancreatitis. Usually, it fades out with real pancreatitis.

DR WYMAN: It would make a difference how long it was going on.

DR DICK: But we have been surprised how many times it is preserved with retroperitoneal tumor in this area.

DR WYMAN: I agree.

The examination of the colon shows the mass described pressing on the sigmoid and overlying the right sacrum. Going back to the original film, the soft-tissue density over the sacrum is not very impressive. These are portable films of the chest taken in an effort to determine the cause of the pain, and there is certainly some fluid in the left costophrenic sinus, laterally and posteriorly, and a suggestion that there might be an infarct in that area. But these are poor films.

DR DICK: Is the liver shadow dense in the left-hand film?

DR WYMAN: I think this is still dye in the gall bladder.

DR DICK: That persisted for some time?

DR WYMAN: Two days actually. The most puzzling of these films to interpret are those of the gastrointestinal series. I do not know exactly how to interpret them. These are the films of the stomach, and the fluoroscopist was quite sure that the second portion of the duodenum was displaced medially and anteriorly. It seems a little less impressive to me on the films alone. I would think that the duodenum might be displaced anteriorly.

DR DICK: The loop is quite large.

DR WYMAN: It is a fairly good-sized loop.

DR DICK: But no intrinsic change.

DR WYMAN: The mucosal pattern is normal. This spot film shows the loop better. This is a film showing filling of the duodenum and several other films showing a suggestion of a filling defect in the third portion of the duodenum posteriorly, just below the ligament of Treitz. I do not know what to make of it. However, in this film taken in a different projection it is less distinct, I do not know whether this is an apparent defect or a true intrinsic defect. The most difficult thing about this patient to explain is the bizarre appearance of the jejunum and ileum. It shows a wild pattern of mucosa, apparently preserved but abnormal in some ways. It looks thickened with some segmentation in the upper ileum or lower jejunum. I cannot explain the picture.

DR DICK: You do not think that there will be some retroperitoneal lesion?

DR WYMAN: Possibly, with something involving the small bowel, particularly the duodenum.

DR DICK: There is no evidence of pancreatic tumor? Nothing you could diagnose pancreatitis on? I still think she had pancreatitis perhaps with liver disease that preceded the pancreatitis and these lumps would be reaction. The things against that are the initial part of the course, — not very stormy and not very febrile, — which one usually sees with a large, diffuse fat necrosis.

A PHYSICIAN: Could it have been appendicitis with abscess and pylephlebitis?

DR DICK: It is possible that the original paralytic ileus was due to appendicitis. But one does not find an amylase that drops the way this did with appendicitis and pylephlebitis. Amylase changes may occur, but I do not know anything about that. The main reason is the general course of the disease — ordinarily, with pylephlebitis, a stormy, febrile course persists, and the patient is much sicker. It does not sound right to me.

DR MALLORY: Dr Simeone, will you tell us your impression?

DR SIMEONE: This patient was admitted to the hospital with a diagnosis of acute cholecystitis. When we saw her in consultation she did not impress us as having acute cholecystitis because she did not have enough tenderness and spasm in the upper abdomen. She represented an even more confusing picture than is recorded in this history. We did a long series of studies. She complained of pain when asked specifically. However, there were times when she was drowsy during the day. I suppose a great many people become drowsy during the day, but this woman could hardly be aroused. We thought of Addison's disease because of the low chloride and the low sodium, but subsequent studies did not bear that out. She began localizing the mass in the abdomen. It began first as an induration in the right part of the abdomen, well below the costal margin. This mass became better and better defined until it was quite accurately outlined as a round mass, fixed — it did not move with respirations — and extending just below the umbilicus on the right. She then began to develop left-sided abdominal tenderness. We were convinced that we were dealing with an inflammatory lesion because of the displacement of parts of the intestinal tract, the febrile reaction and the white-cell count. Operation was therefore decided upon. On the evening before the day of operation she suddenly died of what we thought was pulmonary embolism. Our working diagnosis during all this treatment was retroperitoneal intra-abdominal abscess due to appendicitis as a first choice and to pancreatitis as a second choice, with a retroperitoneal peritonitis localizing in the right-gutter.

obstruction from cancer the x-ray film is apt to show a breakdown of pulmonary tissue in the form of an abscess cavity. But as we shall see later, no definite cavity is present in the x-ray films in this case, and we are forced simply to assume that a certain amount of infection took place. The next point is the normal white-cell counts and normal differentials, which are stressed frequently throughout this record. Again, I do not believe that they are of significance. I was interested in looking at the record this morning of a private patient in the hospital who has had known cancer for several months with a temperature of 101 to 103°F for at least four weeks. In his case the x-ray study does show an abscess cavity beyond the bronchial obstruction, but his white-cell count this morning is still 9900. It is true, however, that his differential count shows 86 per cent neutrophils and that such a high count was not present in the case under consideration. But, again, I do not believe that there is anything in the blood studies that rules out carcinoma or suggests that another diagnosis such as tuberculosis would be better. In the physical examination there is mention of a patch of bronchial breathing which is of course suggestive of consolidation without bronchial obstruction. But this point does not seem to me of real significance. The blood pressure of 70 systolic, 50 diastolic, is interesting and is of possible significance. I remember that in years past we had cases of bronchiogenic carcinoma that very commonly metastasized to the adrenal glands. But I do not believe that in these cases there was sufficient destruction of the gland substance to account for the persistent low blood pressure. Dr Mallory, is it true that we are seeing fewer adrenal metastases from bronchiogenic cancers these days than in the past?

DR TRACY B MALLORY We still see a good many

DR KING The serum protein was low but not low enough to be of great significance, nor can I get disturbed about the albumin-globulin ratio of 1:1. The prothrombin time of 22 seconds, as opposed to the normal of 16 seconds, is again not really significant. The spinal-fluid gold-sol curve is not helpful. The eosinophil count of 5 per cent on two examinations is borderline, although more attention is being paid to such an eosinophilia than was true in the past. But I do not believe there is anything that points to parasitic disease, periarteritis nodosa or other condition in which an eosinophilia would be expected. The urine examinations are important because of the possibility of a hypernephroma with metastases, but a + test for albumin and a few red cells in the sediment are not sufficient to suggest such a possibility. I checked the textbooks again this morning for the possibility of metastases from a basal-cell carcinoma in order to be sure that my impression that they rarely

metastasize was correct. I find that in Willis's* very recent book on tumors he states that metastases to the lymph nodes are rare and that there is only one case on record in which a basal-cell carcinoma, in the reported case on the forehead, metastasized to bones and lung. That is one case in the literature. I doubt if this is a second one.

Apparently, no search was made for tumor cells in the sputum. This is a little strange in this hospital at the present time. There is no mention of bronchoscopy, and I assume that the patient was too sick for this procedure. There was no indication for intravenous pyelograms.

To date, then, I believe that the evidence is in favor of bronchiogenic carcinoma, and we must now turn to the x-ray films to see what help we can get from them.

DR STANLEY M WYMAN The films were taken with the patient lying on his back, Dr King. That is one reason why they are not of good quality. Probably he was unable to co-operate and too sick to be properly positioned. They do show a sharply defined density in the region of the right middle lobe that ends at the interlobar fissure, with some additional mottled density in the upper lobe, again adjacent to the major fissure. There is some pleural reaction along the chest wall laterally and superiorly. It may be fluid or a thick pleura. This appears to be fairly marked over the apex particularly. The right main bronchus, which is described as being narrowed, can be traced from the carina distally, and the branches going to the lower lobe are fairly well seen. The bronchus going to the upper lobe I cannot see, and I cannot see an obstructing lesion.

DR KING The record says, "right main-stem bronchus."

DR WYMAN I think the report is incorrect. The right main-stem bronchus I can see, and I think I can see the bronchi to the lower lobe.

DR KING When you say "right main-stem bronchus," what do you mean?

DR WYMAN I mean the bronchus as it comes off the trachea.

DR KING I may be wrong, but I thought that the bronchoscopists and chest surgeons talked about the right main bronchus as you have but that when they spoke of the right *stem* bronchus they meant that portion of the right bronchus which is below the upper-lobe orifice and above the opening to the right middle lobe.

DR WYMAN I have not heard of that usage. This is the right main bronchus. The upper-lobe bronchus I cannot see, but I cannot say that it is abnormal because I cannot see it.

DR KING But you can make out a definite narrowing of the right main bronchus?

DR WYMAN No, I do not think I can, that is

*Willis, R. A. *Pathology of Tumors*. 992 pp. St. Louis: C. V. Mosby Co. 1943. Pp. 166-192.

solids and had almost daily vomiting, with abdominal and chest pain. He developed bloody sputum. His course was progressively downhill, and he was transferred to this hospital. He had run a low-grade fever, which did not change with penicillin and streptomycin. The white-cell count was 6450 and 8800.

Physical examination showed an emaciated, pale and dehydrated man. Chest examination revealed dullness to percussion and bronchial breathing over the mid-right chest anteriorly. There were rales over the right-lung field anteriorly and posteriorly. The left nipple was replaced by scabs of psoriasis, and there were other plaques over the trunk and back. The nail beds of the fingers and toes were cyanotic and slightly clubbed. Examination of the joints was negative.

The temperature was 101°F, the pulse 105, and the respirations 20. The blood pressure was 70 systolic, 50 diastolic.

The urine was normal. Examination of the blood revealed a red-cell count of 3,650,000, with a hemoglobin of 11.2 gm, and a white-cell count of 11,300, with a normal differential. A sputum test was negative for acid-fast organisms. The serum protein was 6.12 gm per 100 cc, with an albumin-globulin ratio of 1.1. The nonprotein nitrogen was 26 mg per 100 cc. The prothrombin time was 22 seconds (normal, 16 seconds).

X-ray examination of the chest was reported as follows:

There is a large area of increased density which is relatively homogeneous within the right middle lobe for the most part, although a number of nodular areas seem to extend into the right upper lobe. Inferiorly the density is sharply demarcated by the major septum. Superiorly the involved portion of the lung gradually fades into normal-appearing lung structure. There is a suggestion of narrowing of the right main-stem bronchus at the level of the hilus, which may result from encroachment by an adjacent mass. There is probably some fluid in the right pleural space.

X-ray examination of the hands and feet failed to show any evidence of pulmonary osteoarthropathy. The spinal fluid was normal except for a gold-sol curve of 0012332110. An electrocardiogram showed sinus tachycardia and right-axis deviation.

On the third hospital day the temperature rose to 107°F, where it stayed for eighteen hours. During this period the white-cell count was 10,700. On the following day the temperature dropped to 101°F, and over the course of the next few days it gradually rose. On the sixth hospital day the white-cell count was 7600, with a differential of 71 per cent neutrophils, 21 per cent small lymphocytes, 3 per cent monocytes and 5 per cent eosinophils. A gastrointestinal series was negative. Three urine examinations following admission all showed a + test for albumin and an occasional red blood cell in the sediment.

The patient gradually became incontinent and more difficult to arouse. The temperature averaged 103°F. A repeat differential count again showed 5 per cent eosinophils. The skin lesion of the left nipple was biopsied, and basal-cell carcinoma was reported.

On the eighteenth hospital day the patient died.

DIFFERENTIAL DIAGNOSIS

DR. DONALD S. KING: The next to the last sentence, "The skin lesion of the left nipple was biopsied, and basal-cell carcinoma reported," reminds me of many O. Henry stories, which have an unexpected "snapper" at the end. But in the case in point this is probably not an important climax.

The diagnosis in some ways seems so obvious that contrary to the usual method of attack I will first set up the obvious diagnosis and then try to pick it to pieces. The strong impression from the first paragraph is that we are dealing with a bronchiogenic carcinoma. The first symptom was joint pain, and the patient is reported as having slight clubbing of the extremities. So-called "acute clubbing" has been present in a number of our cases of bronchiogenic carcinoma, but as a rule in these cases the x-ray film has shown periosteal changes. Such changes were not seen in the x-ray films in the present case, but I still believe that the joint pains can be associated with the lung condition. Such clubbing and joint pain are more common in cancer than in tuberculosis. And the whole clinical picture is more characteristic of cancer. In the first place, the patient was a man of forty-eight years, and this is the right age and sex. The symptoms of cough, weakness, weight loss, fever and bloody sputum could have been those of either tumor or infection. He vomited and had chest pain with the vomiting, but the gastrointestinal x-ray films taken later were normal, and there is no reason to believe that there was disease in the gastrointestinal tract itself. Physical examination showed emaciation, pallor and slight clubbing. On the laboratory side there was anemia, and the electrocardiograms revealed right-axis deviation. This whole clinical picture could have been due to tuberculosis as well as bronchiogenic carcinoma, but as I read the story my impression is strongly in favor of bronchiogenic carcinoma rather than tuberculosis.

But let us not be too sure of the diagnosis and let us take up the rest of the evidence and see if it gives any leads that should change our point of view. First, there is the persistent fever, with at one time a temperature of 107°F for eighteen hours. A persistent temperature of 101 to 103°F is not unusual in bronchiogenic carcinoma in which the growth obstructs the bronchus and infection develops beyond this obstruction. But it seems to me that all we can do is to forget the very high temperature for eighteen hours. It is true that when there is suppuration beyond bronchial

DR ZELLER I do not believe he did. The psoriasis was extremely interesting. It was the chronic hyperkeratotic type with lesions on the palms and soles and, in addition, the lesion of the left nipple was one that I have never seen before in psoriasis. We got the information from the patient's wife that this had repeatedly drained bloody serous fluid, not for months, but for years. For that reason we were quite anxious to have a biopsy from the point of view of Paget's disease of the nipple. Dr Bauer was impressed with that as a possibility because a friend of his had died of severe carcinomatosis as a result of metastases from Paget's disease of the nipple. I do not know whether or not this biopsy diagnosis completely rules that out. We were unable to agree that any diffuse vascular disease played a part in the picture unless the psoriasis were connected with Paget's disease. One other thing the patient's wife also stated that disorientation was a prominent feature of this problem, but this varied when he was in the hospital. He was disoriented a great deal of the time. Neurologic examination did not give any information for localizing the lesion in the brain. He did at the onset have severe left-sided headache, which he did not have when here.

DR KING It could have been a cerebral metastasis.

DR ZELLER We thought there could have been one.

CLINICAL DIAGNOSIS

Carcinoma of lung?

DR KING'S DIAGNOSIS

Bronchiogenic carcinoma, involving particularly right middle lobe

ANATOMICAL DIAGNOSES

Bronchiogenic carcinoma, right middle lobe, with metastases to pleura, liver and adrenal glands

Hydrothorax, right

Bronchopneumonia, slight

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed bronchiogenic carcinoma that involved what we believed was the bronchus to the right middle lobe, although the upper and middle lobes were almost completely fused so at first it looked as if it were a part of the upper lobe. There was rather extensive pulmonary involvement throughout the right lung with spreading carcinoma extending to the pleura, which was studded with nodules at the time of death. There was a considerable hydrothorax—nearly a liter of fluid. Metastases were found in the hilar mediastinal lymph nodes. One adrenal gland was completely replaced with tumor and the other showed several small nodules. However, there seemed to be a fairly reasonable amount of adrenal cortex left on this side so I do not think we are justified in concluding that the low blood pressure was necessarily due to adrenal insufficiency. As I remember, there was no blood sodium determination at any time. We did not have permission to examine the head, and I cannot say whether there were cerebral metastases.

the point To recapitulate — the right main bronchus as it bifurcates from the trachea is poorly seen but is grossly normal I think I can see branches going to the right lower lobe I can make no comment about the branches to the upper or middle lobe There is density throughout the entire region, but I cannot outline a true mass

DR KING How much so-called atelectasis in the upper and middle lobes do you find?

DR WYMAN They do not look particularly diminished in size If anything, the right middle lobe looks smaller than usual, but diminution is not a prominent feature, it seems to me

DR KING Is there any neoplasm in the lower lobe?

DR WYMAN Not to any appreciable degree, certainly

DR KING Is this the right leaf of the diaphragm?

DR WYMAN Yes, this appears to be the right I assume the lower, this one, is the left The relative height is a matter of chance based on the position of the x-ray tube when the x-ray film was taken

DR KING Is there anything in the two spot films?

DR WYMAN Nothing that I can make out.

DR KING You are not helping me a bit

DR WYMAN In summary, this looks like a drowned middle lobe with pleural reaction over the right upper lobe, with possibly some intrinsic disease in the base of the upper lobe, I would consider this to be due to bronchial occlusion primarily

DR KING Probably some fluid in the right pleural space?

DR WYMAN I agree — extending over the right upper lobe

DR KING You think that is fluid and not pleural metastases?

DR WYMAN I cannot possibly say, it could be either It does not look nodular, which is against frank metastasis, but the fluid may be due to metastases I do not see how one could differentiate

DR KING As far as I am concerned, it does not give the impression of tuberculosis Do you want to commit yourself?

DR WYMAN I would be much surprised if it were tuberculosis

DR KING This particular nodule seems important to me since I think it is a characteristic tumor nodule

DR WYMAN If I saw it alone in the left chest, I would be happy to say metastatic disease, but together with the extensive process in the right lung, I could not be sure that it is tumor

The other films are not very contributory The feet and hands show no periosteal reaction The stomach and the duodenal cap appear normal

DR KING There is no periosteal change in these bones consistent with what we call acute clubbing?

DR WYMAN No definite change in the terminal phalanges either I cannot draw any more conclusions from the chest films than you can because they are so poor, but we have to suspect an occluding bronchial lesion of the right middle lobe, with possibly intrinsic disease in the upper lobe

DR KING The left upper lobe is normal?

DR WYMAN Grossly normal The patient is turned quite a way around, and the mediastinal shadow overlies it, but it looks fairly clear to me.

DR KING That was the best conclusion I could draw from the x-ray films — that there was evidence of obstruction to the right middle-lobe bronchus These shadows close to the spine are not masses, are they?

DR WYMAN It is impossible to be accurate, I think it represents heart shadow in addition to transverse processes of the spine

DR KING I cannot make a completely satisfactory diagnosis The main question is whether this was primarily a malignant tumor or primarily infection or a combination of cancer and suppuration or cancer and tuberculosis All I can say is that to my mind the evidence points toward bronchiogenic carcinoma involving particularly the right middle-lobe bronchus I have been over in my mind all the unusual infections and tumors but can see no evidence for any of them

DR JOHN W ZELLER The surgeons who had charge of this patient very astutely, I do not know whether correctly or not, wondered if he had diffuse vascular disease or connective-tissue disease They probably wondered that on the basis of the fact that the man had psoriasis There was a definite history from the family that he did have swollen, red joints at one time Dr Bauer and I, who saw him repeatedly, did not find any evidence whatever for the diagnosis of rheumatoid arthritis or periarthritis nodosa or the other group diseases

DR KING Did he have clubbing?

DR ZELLER I do not believe he did. The psoriasis was extremely interesting. It was the chronic hyperkeratotic type with lesions on the palms and soles and, in addition, the lesion of the left nipple was one that I have never seen before in psoriasis. We got the information from the patient's wife that this had repeatedly drained bloody serous fluid, not for months, but for years. For that reason we were quite anxious to have a biopsy from the point of view of Paget's disease of the nipple. Dr Bauer was impressed with that as a possibility because a friend of his had died of severe carcinomatosis as a result of metastases from Paget's disease of the nipple. I do not know whether or not this biopsy diagnosis completely rules that out. We were unable to agree that any diffuse vascular disease played a part in the picture unless the psoriasis were connected with Paget's disease. One other thing the patient's wife also stated that disorientation was a prominent feature of this problem, but this varied when he was in the hospital. He was disoriented a great deal of the time. Neurologic examination did not give any information for localizing the lesion in the brain. He did at the onset have severe left-sided headache, which he did not have when here.

DR KING It could have been a cerebral metastasis.

DR ZELLER We thought there could have been one.

CLINICAL DIAGNOSIS

Carcinoma of lung?

DR KING'S DIAGNOSIS

Bronchiogenic carcinoma, involving particularly right middle lobe

ANATOMICAL DIAGNOSES

Bronchiogenic carcinoma, right middle lobe, with metastases to pleura, liver and adrenal glands

Hydrothorax, right

Bronchopneumonia, slight

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed bronchiogenic carcinoma that involved what we believed was the bronchus to the right middle lobe, although the upper and middle lobes were almost completely fused so at first it looked as if it were a part of the upper lobe. There was rather extensive pulmonary involvement throughout the right lung with spreading carcinoma extending to the pleura, which was studded with nodules at the time of death. There was a considerable hydrothorax—nearly a liter of fluid. Metastases were found in the hilar mediastinal lymph nodes. One adrenal gland was completely replaced with tumor and the other showed several small nodules. THIS AMA — WHAT IS IT?

THE American Medical Association, like any important policy-making body that represents a vital activity, is the recipient of varying degrees of criticism. This solicitude increases when large interests are at stake, as at present, it comes from the press, from elements in the general public, from the medical profession itself.

Such criticism is not to be taken lightly or too readily condemned. Criticism is healthy, it is good for the personal and the corporate soul if constructive and properly directed. Criticism may become the motive power of desired action. Destructive criticism, however — and that is the kind most often encountered — harms many and helps none, aired in public, it creates confusion and distrust in

the minds of those who are frequently not in a position to weigh the evidence or even to know the facts.

Certain questions might be asked of the critics within the ranks of medicine, most of whom believe that they have just complaints, and derive a feeling of pleasure or a sense of importance from proclaiming them. Do they read the Organization Section in the *Journal of the American Medical Association*? In particular, do they read the proceedings of the House of Delegates as published? Do they know who their own delegates are, and do they discuss with them national medical problems? Do they attend their district-society meetings and take any active part in discussing and formulating the policies that they would like to see officially adopted? Do they really know what they are talking about?

Perhaps at this point it might be pertinent to ask just what the American Medical Association really is.

The American Medical Association, gentle reader, if you are a member of your state medical society or your Fellowship in the Massachusetts Medical Society, for instance, makes you automatically one of the 136,000 members of the American Medical Association. You may further, on application to the American Medical Association and on payment of a modest assessment that entitles you also to receive the *Journal of the American Medical Association*, become one of the 76,000 fellows of the organization, eligible to hold office in it and to participate in the work of the scientific sections.

As a fellow you have the privilege of helping to support this organization whose only object of existence is to improve the quality and standards of medical practice. This it constantly works toward through the House of Delegates (your representatives) and the Board of Trustees, through the Judicial Council and the councils on medical education and hospitals, scientific assembly, medical service, pharmacy and chemistry, physical medicine, foods and nutrition, industrial health and national emergency medical service. It does so through the bureaus of health education, legal medicine and legislation, exhibits, investigation, industrial and personal relations and medical economic research. It

serves you and the public through the committees on scientific research, therapeutic research, medical motion pictures, rural medical service, scientific exhibit and therapeutic trials, through the scientific sections and the publications

Being composed of human beings — you and other physicians like yourself — your association may sometimes err in judgment, and may often seem to move too slowly when a swift and unerring decision is needed. If this appears to be the case, discuss the matter in your district society and with your delegates. No good can be accomplished by passing the word of your disapproval up and down Main Street. The only possible result will be a general conviction that the doctors don't know how to run their own business and someone had better do something about it.

If your association in your opinion is at fault then start the correction from within. As so aptly stated, some centuries ago, "It is a foule byrd that fyleth his owne nest."

MEDICAL PRACTICE IN GREAT BRITAIN

ENGLAND's current National Health Service Act that came into effect on July 5, 1948, did not, as Sweet points out elsewhere in this issue of the *Journal*, inaugurate any sudden and explosive change in the distribution of medical care in that country. It was rather the latest step in a series of changes that began with the National Health Insurance Act of 1912. By that act a system of compulsory health insurance was established for nearly all wage earners, resulting in the provision of both medical service and medicines to approximately a third of the population.

In 1929 the Local Government Act increased the number of hospital beds operated by the Government, and in 1936 the Voluntary Hospitals Paying Patient Act opened these institutions to the entire population, whether able to pay or not. During the war years Mr. Churchill's minister of health, in conference with representatives of the medical profession, entered into an agreement for a service to cover all aspects of medical care for almost the whole nation. Mr. Aneurin Bevan, minister of health of the Labour Government, took the next step and put through the present Act

against the opposition of the profession, precipitating the confused and controversial situation that exists today.

The position in which the physician may find himself as a result of this confusion is relatively unimportant and is not the issue at stake in Great Britain or in any country that may choose compulsory insurance as its method of providing a wider distribution of medical care. The real issue is the quality of the service that he will be able to deliver under changed and more difficult conditions of practice.

The situation in England does not necessarily carry any implications of what might happen in the United States were the Government to embark on any scheme of compulsory health insurance. The temper and discipline of the people and economic conditions in the two countries are vastly different, and it may be assumed that the quality of medical education and practice in England has suffered greatly since the beginning of the war. Moreover, conditions of practice in England are almost certain to improve as the country becomes adjusted to its regimen.

Perhaps a system of compulsory health insurance in the United States would be less undesirable than many persons now fear, it is natural, however, that the risks inherent in the change to a system that has apparently worked so poorly elsewhere should be dreaded. Slowly as the social aspects of medical care have developed in this country, under a system of free enterprise — much more slowly than the science of medicine has overtaken its horizons — there is still delivered here the best medical care in the world, and it must not be put in jeopardy without better assurance than has yet been offered that the proposed changes represent an improvement. Every instinct must cry out for caution.

As Dr. Edward D. Churchill recently affirmed, this country, like the rest of the world, is in the midst of a social revolution of which a changing type of medical practice represents only one phase. Already the federal Government is paying a medical bill of \$1,200,000,000 a year, over four fifths of it for the care of the patient. Further crystallization of medicine under Government control could easily inactivate its progress in a phase of evolution that

may well result, if allowed to continue its way unhampered, in a more simplified system of practice with much greater emphasis being successfully placed on the prevention of disease and the improvement of health

"IF YE BREAK FAITH"

DURING nearly sixty years of his long and singularly useful life, Dr Walter P Bowers, first editor of this *Journal* under the ownership of the Massachusetts Medical Society, was associated with the Clinton Hospital Under his guidance it grew from a modest nursing home to a general hospital serving Clinton and its surrounding communities

No task was too humble for Dr Bowers's conception of community service As chief surgeon of the hospital he was not above serving as orderly when the occasion required, wheeling his patients to the operating room, carrying them from the truck to their beds As the hospital outgrew and wore out its facilities for discharging its obligations to the area it serves, in 1944 he set his hand to his last task as president of the Hospital, at the age of nearly ninety, in the collection of a fund for a new hospital building This fund was oversubscribed, but rising costs did not permit the completion and equipment of the building

The story and the present needs of the hospital are told elsewhere in this issue of the *Journal* in a communication from Henry F Bigelow, who succeeded Dr Bowers as president of the Clinton Hospital

Funds for the completion of the memorial building have been made available by the federal Government in the stated ratio to community effort, and on his death in 1947 it was disclosed that Dr Bowers had left the sum of \$100,000, nearly all his life savings, as his final contribution to the welfare of the communities that he had spent his life in serving This bequest cuts to a relatively modest sum the amount needed to make the federal grant effective and bring the Walter P Bowers Memorial to completion

Even in these unsettled days there can be no thought that the citizens of Clinton and its surrounding countryside and Dr Bowers's other friends will permit this vital enterprise to fail

BIBLIOGRAPHIA INTERMINATA

THERE has been a growing tendency among American men of letters (medical) finally to seal the products of their pen with that last authoritative stamp of literary righteousness, the replete bibliography Like the tail of a kite or the ballast on a yacht's keel it hangs there, keeping its vehicle right side up by sheer weight alone

The *Journal*, as much as any other medical periodical, has been guilty of failing sufficiently to discourage this tendency so universal among today's medical authors It has seemed unkind to criticize the tangible result, in 6-point type, of so much labor

The editor of the *Journal of the American Medical Association* is more forthright In his opinion

It is no longer excusable to bolster a report of a case or an article with a compilation of references to all similar cases that have been reported in the literature The growth of medical literature has made this not only a useless but also an unwarranted task Reference should be given only to articles that illuminate the subject To republish long bibliographies taken from other authors is a form of plagiarism which burdens the literature with uninteresting and worthless lists of titles¹

The *London Lancet*, keen-edged as at any time in its century and a quarter of existence, has noted this transoceanic tendency and commented on it, not unkindly²

[²⁷, ³⁸, ¹¹⁶ think that⁴⁶, ⁷⁶ this method,³, ²² ³⁴ ³⁰³ of citing references⁸ to published papers¹⁶, ⁴², ⁹², ¹¹⁷ is rather over done²¹, ⁷⁴, ¹¹⁰ by some workers,⁹¹, ¹⁴² ⁴⁰⁵ ⁵¹² particularly American authors²⁵, ³⁸ ⁷⁸, ⁸⁵, ¹¹², ²¹⁰ ⁵¹² of review articles, et al

NOTES FROM THE MEDICAL EXAMINER

THE APPLICATIONS OF SPECTROPHOTOMETRY TO MEDICINE

The development of simple, reliable ultraviolet and visible spectrophotometers within the last ten years has made available an analytical tool of great versatility and power The role played by spectrophotometric methods in research on vitamins and hormones has been spectacular¹ the application of these methods to analytical procedures promises to be equally impressive

Spectrophotometric methods possess certain advantages that are particularly desirable in toxicologic investigations the results are subject to qualitative interpretations having fundamental structural chemical significance, they are quantitative, the procedure is direct and simple, and the results reproducible, and the sample is not consumed

Spectral curves are obtained by the plotting of variations of optical density of the solution with respect to wave length of light In the ultraviolet and visible regions such curves are characteristic of certain molecular configurations, generally involving chemical unsaturation The benzene and pyridine rings, or the benzoyl and phenol groups, are typical easily recognizable structural entities Compounds containing such groups will generally exhibit absorption spectrums closely related to the parent groups

Quantitatively, spectrophotometric methods depend upon the same laws as visual colorimetry the optical density of the solution is proportional to the amount of material present The ability of a chemical to absorb light of a given wave length is expressed by the molecular extinction ϵ , which is the optical density of a molar solution in a 1-cm light path The greater the molecular extinction of the compound, the more sensitive becomes the spectrophotometric method for its detection Useful molecular extinctions in the ultraviolet region range from values as low as 200 to as high as 50,000 These generally permit determination of a compound when present in the order of 100 to 1 microgm

In practice it is rare that a determination of a compound can be made by the light absorption at a single wave length without interference from absorption by other chromogens If the interfering chromogens cannot be removed readily by chemical or physical means, it becomes necessary to evaluate their contribution to the total light absorption This is most frequently accomplished in a two-component system by a second determination of optical density at a wave length chosen because the contributions of the two components to the total density are inversely related²

Carbon Monoxide

Advantages of spectrophotometric methods over conventional gasometric methods are well illustrated in the determination of the degree of saturation of blood with carbon monoxide Gasometric methods, although of high precision when carried out on fresh blood under ideal routine conditions, are laborious, technically difficult and, in the examination of putrid blood, inaccurate Reasonably precise, inherently accurate analyses can be achieved by any of several spectrophotometric means, none of which are technically difficult²⁻⁴ The method of Schmidt,⁴ in which the spectral characteristics of carboxy-hemochromogen are employed, appears to be applicable even to putrid blood

Barbiturates

The simplicity and sensitivity of spectrophotometric procedures are illustrated by recent methods for the detection and determination of barbiturates and thiobarbiturates in blood Pentothal, a thiobarbiturate, exhibits a pronounced absorption band at 288 microns in ether⁵ and 285 microns in chloroform,⁶ and a related band at 305 microns in aqueous alkali⁶ By very simple extractive procedures it is possible to estimate as little as 0.35 mg per 100 cc of pentothal in 1 cc of plasma In the detection of the barbiturates the fact that ϵ at 240 millimicrons changes from 0 at pH 2 to 10,000 at pH 10 has formed the basis of a relatively specific method in which the interference of other chromogens is reduced to a minimum⁷

Phenols

Phenol exhibits strong ultraviolet absorption in acid solution When the solution is made basic the absorption peaks shift toward the visible end of the spectrum The influence of pH on the character of the absorption curve can serve both as an important factor in identification and as a basis for quantitation

Salicylic Acid

This acid, closely related to phenol, is of importance clinically and in many medicolegal deaths It may be estimated by the barbiturate method of Walker, Fisher and McHugh⁷ When it occurs together with barbiturates in blood, it may be separated from them by extraction of a chloroform solution with an aqueous solution buffered at pH 7

Alkaloids

Many of the common alkaloids exhibit useful absorption spectrums in the ultraviolet region^{8,9} Morphine, which has a phenolic structure, possesses a corresponding spectrum The spectrum of nicotine is closely related to that of pyridine and nicotinic acid^{1,9} Ultraviolet spectrophotometry is one of the most convenient and sensitive methods for its detection and determination The ultraviolet absorption spectrum of cocaine appears to be due to the benzoyl group, and the spectrums of atropine, hvocyanine, ephedrine and amphetamine to the substituted benzene ring Strychnine, brucine and quinine likewise possess characteristic and useful spectrums

AMERICAN HOSPITAL ASSOCIATION

The American Hospital Association, according to the *New York Times*, representing the majority of the nation's hospitals, has gone on record as opposing any further extension of Government supervision in the health field. All legislative proposals to date, including the "Nation's Health" report of Federal Security Administrator, Oscar R. Ewing, were described as "administrative monstrosities" by George Hughes, executive director of the Association. Declaring that administration was the important factor in the health plan, he said that, "The confusion in the present federal activities is not an incentive to turn over to the government all the health activities of the nation."

CORRESPONDENCE

WALTER P BOWERS MEMORIAL

To the Editor I am sure many of the readers of the *New England Journal of Medicine* need no introduction to Dr Walter Prentice Bowers, who served as its editor from 1920 to 1937. A full account of Dr Bowers's life and accomplishments, as well as his civic and humanitarian contributions, appeared in the issue of September 25, 1947.

Your readers, however, may not know that Dr Bowers left a very substantial part of his estate to the completion of the new Clinton Hospital, which he founded in 1889 and of which he was the first president for fifty years. Work on the new hospital had started before Dr Bowers died in 1947. However, the original Building Fund raised in 1944-1945 proved inadequate because, when it was possible to start construction after the war, costs had advanced substantially. Through the co-operation of Dr Vlado A. Getting, Massachusetts commissioner of public health, a federal grant of approximately \$225,000 was approved under the terms of Public Law 725, the Hospital Survey and Construction Act. Payment of this grant, however, as the act provides, is contingent on our making available funds to cover two thirds of the total cost of completing the building, the empty shell of which now stands. In other words, the Government will pay one dollar toward completing the hospital if we can provide the other two dollars necessary.

We are now engaged in a completion fund campaign of \$275,000, the success of which is essential for us to take advantage of the federal grant. It has occurred to our trustees that some of Dr Bowers's friends might wish to make contributions toward the Walter P. Bowers Memorial Building, a three-story modern plant of 75 beds with up-to-date facilities, designed by Coolidge, Shepley, Bulfinch and Abbott. Dr Charles F. Wilinsky, of Beth Israel Hospital, has served as our consultant.

I hope that you will consider it quite proper for me to bring this matter to your attention as I have. All of us in Clinton and in the surrounding towns that make up our hospital area of 25,000 people are serious in our purpose to complete this lasting memorial to a truly great physician and citizen, and we would like to offer this opportunity to others who may be of the same mind to give us a lift in this undertaking.

ANNOUNCEMENT

Dr Robert Salwen announces the opening of his office at 158 Suffolk Street, Holyoke, for the practice of urology.

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

30 Bennet Street, Boston

Lecture Hall, 9-10 a m

MORNING CONFERENCE PROGRAM

- Wednesday, February 9 — Pediatric Clinicopathological Conference Drs James M. Baty and H. E. MacMahon.
- Friday, February 11 — Some Physiologic Considerations of Congestive Heart Failure Dr Richard Bloomfield
- Tuesday, February 15 — *Journal Review*
- Friday, February 18 — Poliomyelitis Management in the late stage Dr Joseph S. Barr
- Tuesday, February 22 — Holiday — No Conference
- Friday, February 25 — Recent Developments in Group Practice Dr Franz Goldmann

From 9 to 10 o'clock on Wednesday, Thursday and Saturday mornings clinics will be given by members of the hospital staff. Medical rounds are conducted each weekday except Saturday by members of the hospital staff from 12 to 1 p.m. On the second and fourth Fridays of the month, February 11 and 25, Therapeutic Conferences will be held with round-table discussion from 2 to 4 p.m., with Dr Robert P. McCombs as moderator. On the second and fourth Fridays, February 11 and 25, Dr Merrill Sosman will conduct x-ray conferences from 4 to 6 p.m.

All exercises are open to the medical profession.

HARVARD MEDICAL SOCIETY

A meeting of the Harvard Medical Society will be held in the amphitheater of Building D, Harvard Medical School, on Tuesday, February 8, at 8:00 p.m. The chairman for the evening will be Dr Herrman L. Blumgart.

PROGRAM

- Transmural Migration of Intestinal Bacteria into the Peritoneal Cavity Fritz Schweinberg
- The Effect of Polyvinyl Alcohol on the Growth of the Diphtheria Bacillus Sidney Cohen
- Some New Methods for the Histochemical Identification of Enzymes Arnold M. Seligman and Marvin Nachlas
- Purification, Physiologic and Biochemical Properties of Prothrombin Conversion Accelerator in Serum Benjamin Alexander, Greta Landwehr and Robert Goldstein
- The Biologic Effects of Radioactive Iodine (¹³¹I) on the Normal Thyroid Gland and Other Tissues in Man A. Stone Freedberg, George Kurland, Alvin Ureles and Saul Hertz

Subsequent meetings will be held on March 8, April 12 and May 10.

NEW ENGLAND SOCIETY OF ANESTHESIOLOGISTS

A meeting of the New England Society of Anesthesiologists will be held in the Auditorium of Building A, Boston University School of Medicine, 80 East Concord Street, Boston, on Tuesday, February 8, at 8:00 p.m. The scientific program will consist of the following:

- Medical Malpractice Chas. J. Dunn, LL.B., legislative counsel for the Massachusetts Medical Society
- Is there a Threat of Political Medicine? John F. Conlin, M.D., Director of Medical Education and Information, Massachusetts Medical Society

Physicians and medical students are invited

ELECTROSHOCK THERAPY IN DEPRESSIVE STATES*

Experience in a General Hospital

SIMON STONE, M.D.†

MANCHESTER, NEW HAMPSHIRE

SINCE its introduction by Cerletti and Bini¹ in 1938, electroshock therapy has become an accepted therapeutic procedure and has replaced metrazol as the most effective therapeutic convulsive agent. It has been found most useful in depressive states of a manic depressive nature, involutional depressions and involutional paranoid conditions and in depressions of later life and also as an adjunct in the treatment of psychoneuroses with depressive coloring. It has replaced insulin in the treatment of some early cases of schizophrenia, and has been used experimentally in a large variety of neuropsychiatric conditions including general paresis,² Parkinson's disease,³ tics,³ stammering,⁴ drug addiction and alcoholism,⁵ with indifferent results in many cases.

Electroshock treatment has been mostly limited to state psychiatric institutions and private psychiatric hospitals and occasionally ambulatory office treatment of well behaved, co-operative patients. The office treatment has been frowned upon,⁶ however, in view of the inadequacy in most cases of office facilities for close supervision of patients during and after treatment and the danger of an unexpectedly fatal outcome or the development of severe complications. Such emergencies as respiratory embarrassment, acute disturbed postconvulsive states, fractures or dislocations may be difficult to manage in a physician's office. Authorities in general hospitals have also been reluctant to admit any patients even with mild psychiatric disorders for psychiatric treatment, although the same patients were frequently admitted for a surgical procedure or medical care without hesitation. The reason usually given was that adequate facilities were not available for proper care of such patients in the hospital, and also that the presence of these patients might become upsetting to others. Although it must be admitted that hospitalization of an

agitated patient for prolonged psychiatric treatment in a general hospital in the present crowded condition of such hospitals might arouse justifiable criticism, the hospitalization of a patient for a course of electroshock therapy for a period of ten days or two weeks should not be considered any different from hospitalization for a surgical operation. The urgency is just as great in one case as in the other, and in the communities where no adequate private psychiatric facilities exist this is at times a godsend.

The Elliot Hospital in Manchester and the Concord Hospital have been accepting patients for electroshock therapy for several years, and so far the hospital authorities have had no reason to regret this decision. It was found that some patients in a mildly agitated and apprehensive state could be safely handled in a ward or in a private room till after the first or second electroshock treatment. Usually, the agitation subsides after a few treatments and the improvement that follows often makes close supervision unnecessary.

The advantage of treatment in a general hospital is that any additional studies such as electrocardiograms, x-ray studies and urine and blood examinations can be carried out whenever indicated, without the need of transferring the patients to a general from a psychiatric hospital for such studies as is occasionally the procedure. Also, services of consultants, including cardiologists, orthopedic surgeons and bronchoscopists, are readily available if the need should arise. The fact that the depressed patient can enter a general hospital for special treatment has acted as an emotional booster after recovery has taken place, in that it helped to remove the stigma of admission to a specialized "insane" hospital for treatment, and the emotional trauma that is occasionally associated with such an experience is thus obviated.

The psychiatrist benefits from the hospitalization in that any psychotherapy indicated can be carried out while the patient is in the hospital, and the hospital resident medical and nursing staffs

can often be utilized for added indirect psychotherapy. From a teaching point of view, the medical residents can see these patients and follow up their progress and response to treatment. No special facilities are required except a room with a Gatch bed, electroshock apparatus and a nursing team. One nurse assistant experienced in electroshock therapy is sufficient, and usually other nurses can be recruited easily from the regular nursing staff.

The usual number of treatments given to patients that I have treated has been five to seven administered every other day. When electroshock therapy was first introduced it was deemed advisable to administer twelve to twenty treatments as a minimum to most patients in a depressive state. The greatest number of treatments is still being used by many psychiatrists, but I have found that if the patient is going to improve, the major gains generally become apparent after the fourth or fifth treatment and the gain after subsequent treatments is often only minor. I have found it safe to discharge hospitalized patients after such a brief course of treatment, if in the opinion of a responsible member of the family the patient has reached the prepsychotic level. However, in depressed patients with paranoid delusions of long standing a greater number of treatments may be required to prevent a relapse.

The average hospitalization time was about fourteen days for out-of-town patients. Local residents with a satisfactory home environment and an understanding and co-operative family have been treated on an ambulatory basis, the patients remaining in the hospital for several hours after the treatment was completed to assure complete recovery from its aftereffects before they were allowed to leave for home in the company of a member of their family. All hospitalized patients are seen within a week of discharge from the hospital and are followed up at regular intervals. The family is also advised to communicate with the physician immediately if any untoward change takes place in the patient's condition.

I have found electroshock therapy most useful in cases of involutional melancholia and depressive reactions, either manic depressive or reactive depressions. The recovery rate has been raised in these cases, and the duration of the illness reduced about 75 per cent. It is now possible in many cases to abort a depressive attack with five or six electroshock treatments in a period of two weeks instead of the average duration in the past of from six to eighteen months.

Patients with involutional melancholia, who were formerly treated for long periods with estrogens without striking results and who either recovered on their own after several years of illness or finally required hospitalization in a psychiatric hospital, now show an 85 per cent incidence of recovery following electroshock therapy. Relapses have been

uncommon in the cases treated, and in the relapsed cases an unsatisfactory home environment, which often was beyond the psychiatrist's control, contributed to the relapse. Recurrence of depressive attacks in patients treated with shock therapy is not greater than in those who recovered under conservative therapy, and in some patients prone to recurrences this can be aborted by the administration of one or more treatments regularly at monthly or bimonthly intervals.

I have also found electroshock therapy of value in early cases of schizophrenia, in selected cases of anxiety and conversion hysteria, especially those with depressive features, and also in 2 cases of obsessive compulsive neurosis in which the patients failed to improve under conservative therapy, the procedure was used as a remedy of desperation in these cases. In another case the therapy was administered when the patient had failed to improve after prolonged hospitalization in a psychiatric hospital. The obsessive fear of handling knives and compulsion of having to cause harm to members of her family had resulted in the patient's separation from her younger children for several years. The intensity of the fears and compulsions became greatly reduced after five electroshock treatments. In the end she was able to discuss these fears in an impersonal manner, and although they did not entirely disappear she did not seem to be troubled by them to any extent and was able to resume full care of her children.

The oldest patient treated was seventy-two and the youngest twenty years old. Age is no contraindication to treatment, and many depressions of later life respond well to electroshock therapy. One patient had auricular fibrillation and also a right-sided hemiparesis. She was exhausting herself physically from her continuous agitation, impaired sleep and worry over real and imaginary transgressions in the past. The cardiac consultant believed that in view of her poor prognosis without treatment as far as her cardiac condition was concerned, the risk of electroshock treatment was worth taking. She tolerated the treatments well. At the end of a course of six treatments the agitation subsided, self-accusatory ideas disappeared, and she was able to resume her normal activities. Her heart function also improved with the removal of contributing psychogenic factors. The hemiplegia was not aggravated by the treatment, and a constant severe pain in the paralyzed shoulder of which she complained before treatment also disappeared.

There have been no serious complications in any of the cases treated. It is a safe procedure when properly supervised and the mortality is no greater than that for a general anesthetic. In a survey of deaths from electroshock therapy in all American hospitals, Kolb and Vogel⁷ found a mortality figure of 6 per 10,000 or about one tenth the death rate for patients treated with insulin shock. The mor-

tality is slightly higher, however, in curare-treated cases, and many psychiatrists limit the use of curare to patients with suspected brittle bones, pre-existent fractures or extreme muscularity. I have used it only when there was a potential danger of bone fractures or in very muscular patients.

Postconvulsive excited states can be avoided in most cases by intravenous injection of 0.3 to 0.5 gm of sodium amytal about ten or fifteen minutes before treatment. This complication occurred in 2 male patients and was relieved by sodium amytal injections. I have been taking this precaution routinely in strong, muscular persons who showed any evidence of excitement after the first treatment to avoid injury to the patient during this confused state.

Memory impairment is also a frequent transitory complaint, and its severity parallels the number of treatments administered. It usually clears up in a period of several weeks, and impairment is greatest in fields of recall and concentration. Respiratory embarrassment is more common in the curare-treated cases, although I have observed none in the cases I have treated so far. The use of a respirator or artificial respiration generally restores breathing to normal.

No fractures occurred in any of the cases treated. Dislocation of the jaw occurred in the same patient on two occasions and was easily reduced before this patient regained consciousness.

CASE REPORTS

CASE 1 M M, a 21-year-old woman, had felt depressed for about 3 months, lost interest in her friends, slept poorly and expressed death wishes. She planned to be married in a month, but failed to take any interest in the arrangements for her wedding. She also gave up her work at the onset of her illness. Before the present symptoms came on she had had a period of overactivity when she talked excessively, was flighty in her ideas, wanted to be on the go, had many plans, made some foolish purchases and spent her money lavishly.

During the psychiatric interview she was slow in her responses, was unable to elaborate on her symptoms and gave perfunctory answers. She complained of having lost her ambition and said she did not care whether her forthcoming marriage was to take place. She admitted feeling depressed and wishing she were dead. After the second electroshock treatment she talked more freely about herself, appeared more cheerful and showed interest in ward routine and in other patients. After the fifth treatment she developed a mild hypomanic state when she laughed out without evident cause, had a number of plans for her wedding and appeared exuberant and full of energy. This phase subsided in 2 days. She was discharged from the hospital 2 weeks after admission, appearing "like her usual self," according to her parents. She showed good judgment and insight during follow-up interviews and was reported to be in good mental health a year after her discharge from the hospital.

The diagnosis was that of a manic depressive, depressive reaction, with good recovery following electroshock therapy.

CASE 2 L D, a 45-year-old woman with a diagnosis of involutional melancholia had been depressed for about 1 year and had given up her job as a business executive 6 months earlier. She blamed this action on her inability to concentrate, fears of losing her mind and continuous preoccupation and guilt feeling over poor business investments (the last being untrue). She received estrogen injections for over 1

year without improvement. She recovered after five electroshock treatments, and was able to return to work 5 weeks after the treatments were begun. She was treated on an ambulatory basis. She had continued in good mental health for 1 year after the treatments had been completed.

CASE 3 G G, a 49-year-old woman, had been depressed, self-accusatory and apprehensive for 2 years. She became obsessed with many religious ideas, blamed herself for the neglect of her family and refused to allow her husband to go to work for fear of some harm befalling him when he was away from her. She had received estrogenic therapy, various sedatives, and iron and liver for her anemia, without improvement.

When she was admitted she was very apprehensive, and it was doubted whether she could be cared for in a general hospital. Much persuasion had to be used before the first treatment could be given. After this treatment she appeared more relaxed and co-operated well in the other five treatments. She made an excellent recovery after 2 weeks of hospitalization, and has been doing her housework, and her own shopping, which she did not do before admission for treatment. The self-accusatory ideas have disappeared, and she shows good insight. Her husband has also been able to return to his job. As she described it "she has not felt so well for years." She complained of some impairment of memory for several weeks after her return home, which was somewhat annoying at first, but later she found that by taking her time she had no difficulty whatsoever in recalling past events.

The diagnosis was that of involutional melancholia, with good recovery.

CASE 4 J N, a 57-year-old man, developed what he described as a nervous breakdown 2 years previously. He felt discouraged, worried about the loss of his job, failed to enjoy doing things that gave him much pleasure in the past and blamed himself for neglect of his family and his job. He was treated with testosterone, sedation and vitamins, but symptoms continued and he had to give up his job.

He had had a "nervous breakdown" 14 years earlier, which lasted a number of months.

Electroshock therapy was recommended, but he believed that he could benefit more from a few months of rest on a farm. After he failed to improve under this regime, he was given four electroshock treatments, for which he was hospitalized for 2 weeks. He tolerated the treatments well except for a postconvulsive excited period, which lasted for about 10 minutes after the second treatment. He made an excellent recovery and returned to work 10 days after leaving the hospital and has been regularly employed since. The anhedonia and self-accusatory ideas have disappeared, and he enjoys all his former activities.

The diagnosis was that of recurrent depressive reaction with involutional features.

DISCUSSION

It has been estimated that for a community with a population of about 100,000 an average of 12 psychiatric beds set apart in the general hospitals in that community would be a minimum requirement.⁸ When one considers that only about 1 in 5 new patients admitted to a state hospital require care on a disturbed ward, and that early diagnosis and treatment frequently aid in aborting a psychotic attack or reduce its severity so that such a patient can be adequately cared for in a general hospital, it becomes obvious that the better the facilities in a general hospital for the care of such patients, the lighter the burden for the state hospital.

The advantages of general-hospital care are that the hospital stay is greatly reduced for the reason that patients are usually worked up faster and any treatment needed is immediately applied. There has been a tendency in state hospitals because of

can often be utilized for added indirect psychotherapy. From a teaching point of view, the medical residents can see these patients and follow up their progress and response to treatment. No special facilities are required except a room with a Gatch bed, electroshock apparatus and a nursing team. One nurse assistant experienced in electroshock therapy is sufficient, and usually other nurses can be recruited easily from the regular nursing staff.

The usual number of treatments given to patients that I have treated has been five to seven administered every other day. When electroshock therapy was first introduced it was deemed advisable to administer twelve to twenty treatments as a minimum to most patients in a depressive state. The greatest number of treatments is still being used by many psychiatrists, but I have found that if the patient is going to improve, the major gains generally become apparent after the fourth or fifth treatment and the gain after subsequent treatments is often only minor. I have found it safe to discharge hospitalized patients after such a brief course of treatment, if in the opinion of a responsible member of the family the patient has reached the prepsychotic level. However, in depressed patients with paranoid delusions of long standing a greater number of treatments may be required to prevent a relapse.

The average hospitalization time was about fourteen days for out-of-town patients. Local residents with a satisfactory home environment and an understanding and co-operative family have been treated on an ambulatory basis, the patients remaining in the hospital for several hours after the treatment was completed to assure complete recovery from its aftereffects before they were allowed to leave for home in the company of a member of their family. All hospitalized patients are seen within a week of discharge from the hospital and are followed up at regular intervals. The family is also advised to communicate with the physician immediately if any untoward change takes place in the patient's condition.

I have found electroshock therapy most useful in cases of involutional melancholia and depressive reactions, either manic depressive or reactive depressions. The recovery rate has been raised in these cases, and the duration of the illness reduced about 75 per cent. It is now possible in many cases to abort a depressive attack with five or six electroshock treatments in a period of two weeks instead of the average duration in the past of from six to eighteen months.

Patients with involutional melancholia, who were formerly treated for long periods with estrogens without striking results and who either recovered on their own after several years of illness or finally required hospitalization in a psychiatric hospital, now show an 85 per cent incidence of recovery following electroshock therapy. Relapses have been

uncommon in the cases treated, and in the relapsed cases an unsatisfactory home environment, which often was beyond the psychiatrist's control, contributed to the relapse. Recurrence of depressive attacks in patients treated with shock therapy is not greater than in those who recovered under conservative therapy, and in some patients prone to recurrences this can be aborted by the administration of one or more treatments regularly at monthly or bimonthly intervals.

I have also found electroshock therapy of value in early cases of schizophrenia, in selected cases of anxiety and conversion hysteria, especially those with depressive features, and also in 2 cases of obsessive compulsive neurosis in which the patients failed to improve under conservative therapy, the procedure was used as a remedy of desperation in these cases. In another case the therapy was administered when the patient had failed to improve after prolonged hospitalization in a psychiatric hospital. The obsessive fear of handling knives and compulsion of having to cause harm to members of her family had resulted in the patient's separation from her younger children for several years. The intensity of the fears and compulsions became greatly reduced after five electroshock treatments. In the end she was able to discuss these fears in an impersonal manner, and although they did not entirely disappear she did not seem to be troubled by them to any extent and was able to resume full care of her children.

The oldest patient treated was seventy-two and the youngest twenty years old. Age is no contraindication to treatment, and many depressions of later life respond well to electroshock therapy. One patient had auricular fibrillation and also a right-sided hemiparesis. She was exhausting herself physically from her continuous agitation, impaired sleep and worry over real and imaginary transgressions in the past. The cardiac consultant believed that in view of her poor prognosis without treatment as far as her cardiac condition was concerned, the risk of electroshock treatment was worth taking. She tolerated the treatments well. At the end of a course of six treatments the agitation subsided, self-accusatory ideas disappeared, and she was able to resume her normal activities. Her heart function also improved with the removal of contributing psychogenic factors. The hemiplegia was not aggravated by the treatment, and a constant severe pain in the paralyzed shoulder of which she complained before treatment also disappeared.

There have been no serious complications in any of the cases treated. It is a safe procedure when properly supervised and the mortality is no greater than that for a general anesthetic. In a survey of deaths from electroshock therapy in all American hospitals, Kolb and Vogel⁷ found a mortality figure of 6 per 10,000 or about one tenth the death rate for patients treated with insulin shock. The mor-

used would eventually aid materially in relieving some of the load in overcrowded state and private psychiatric hospitals

PRESIDENTIAL ADDRESS*

DAVID W PARKER, M D †

MANCHESTER, NEW HAMPSHIRE

MANY of the senior group of this society have had the rare opportunity of observing the growth of the art and science of modern surgery from a scope that, judged by present standards, was extremely limited to its present almost unbelievable heights. This development has carried with it serious responsibilities to the surgical profession, and also grave problems in the training of prospective surgeons to cope with the highly diversified and technical procedures that it will be necessary for them to master if they are to take their place as specialists in surgery. There have also been problems of raising the standards of hospital care, expansion of laboratory facilities and refinements of record systems and the limitation of incompetent and unnecessary surgery.

Volumes have been written and published through the years by leaders in the surgical field dealing with these problems. The efforts of the American College of Surgeons and, later, of the American Board of Surgery have been of inestimable value in correcting many of the existing weak spots in the practice of surgery. However, many phases of the situation have not been and probably cannot be, reached by these bodies without a fuller program, and definitely more decisive action by organized groups of surgeons who are in a position to mold the conscience and ideals of surgeons in general in their sphere of influence — for example, the New England Surgical Society in New England.

One hesitates to speak on the training of surgeons before a group who have recently listened to the excellent papers by Lanman¹ and Harvey² on this subject. These men have admitted that the train-

ing of surgeons has become too great a load for the teaching hospitals and although many references have been made to the possibility of training surgeons in the smaller hospitals, no positive action has been taken to supplement these suggestions. After forty years of surgical practice in a smaller community, one develops some ideas on this subject, and I hope to present to you a plan, and I use this word guardedly, that may eventually bring the outlying medical communities into the orbit of teaching institutions.

Until recently, there have been two schools of surgical teaching in this country: the prolonged period of carefully supervised training in teaching hospitals and clinics, and the method of trial and error used by general practitioners to perfect themselves gradually in the art of surgery. It was standard practice some years ago for a physician to begin in general practice and work into surgery gradually, and, had it not been for this self-training, much of the necessary surgery in the smaller hospitals would have gone undone. Today, such a practitioner has to ask a fully qualified surgeon to assist him in operations on appendixes, hernias and gall bladders and up the scale until he has developed enough dexterity to operate fairly safely. And all the while that the senior surgeon is keeping him out of trouble and guiding him through the maze of surgical technic and postoperative care, the novice collects the fee and poses as the surgeon. Today, such a practice is unnecessary, and all too often exploits the surgeon who is asked to assist. The American Board of Surgery and American College of Surgeons have done much to discourage this practice by listing minimal requirements of training before a physician is admitted to the surgical staff of a hospital. But the practice will not disappear until every recognized hospital adheres rigorously to these requirements.

shortage of staff physicians and for other reasons to postpone treatment in new admissions till a staff diagnosis is made, which often delays active treatment for some time. At comparatively little cost in even the smaller hospital several rooms can be easily remodeled to give adequate temporary care to any acute psychiatric emergency that might arise without disturbance to other patients. Acute confused and excited episodes are not too infrequent after surgical procedures, or deliveries, in cases of acute cardiac decompensation, anemias and other blood dyscrasias and in cases of cerebral metastatic neoplastic growths. If better facilities were available for the care of such patients in a general hospital, the need for transfer of patients with acute cardiac disorders some distance to a state hospital during a disturbed episode would be avoided. Not infrequently, such patients arrive at the hospital in a moribund condition and die shortly after arrival, much to the chagrin of the state-hospital staff. Attention has been called to this situation and also to the fact that a physician may become liable for malpractice for the unwarranted transfer of a patient to another hospital when the patient's condition is apt to suffer from such a change.⁹ It has been planned, therefore, for at least four rooms to be set apart and equipped at the new unit of the Elliot Hospital for the care of any acute and subacute psychiatric problems that show promise of rapid improvement under proper care.

The mode of action of electroshock therapy is still unknown. Most likely it acts as a bloodless frontal lobotomy, reversible if a moderate number of treatments are given, and just as severe in its aftereffects after too many treatments. The effects are probably not limited to the cortex alone, but also involve the autonomic centers in the midbrain, the pituitary body and, indirectly, the gonadal system. The extinction of undesirable patterns of behavior in animal experiments has been described by Masserman and Jacques¹⁰ after electroshock therapy — at the cost, however, of impairment of some of the higher integrative functions. If the psychosis or neurosis is sufficiently disabling and has not responded to conservative therapy, electroshock treatment appears to be preferable to continuation in the previous state even at the risk of some memory impairment.

There is still considerable divergence of opinion about the value of electroshock therapy in the psychoneuroses. I have seen cases of anxiety neurosis definitely aggravated by electroshock therapy administered elsewhere, improvement was observed after the shock therapy had been discontinued and the patient had been reassured that no more shock treatments were forthcoming and helped toward a better social adjustment, with special attention to sleep and nutritional habits. My impression is that the high rate of improvement reported by some observers¹¹ with electroshock

therapy in cases of psychoneurosis is due to the fact that many of these patients really belong in the cyclic group of disorders, with the symptoms of anxiety and somatic discomforts actually representing a manic depressive, depressive equivalent. Such patients can often deceive even the best trained observer, and the somatic symptoms may be so vividly described and acted out by the patient that the patient often parts with a different organ with each depression at the hands of some eager surgeon. Not infrequently, recovery follows each surgical procedure, as a result either of the effects of the anesthesia (or the emotional release associated with feelings of penance and sacrifice that accompany organ removal in some persons) or the patient's removal to the restful, friendly and solicitous hospital atmosphere from an uncongenial home environment, the recovery may be due to a combination of all factors. These cases are often diagnosed as psychoneurosis, and no doubt the patients benefit from electroshock therapy in that the attacks can be aborted, although the incidence of recurrence is not affected by the treatment. In my own experience electroshock therapy is indicated in about 5 to 10 per cent of cases of psychoneurosis and should then be used only after the patient has failed to improve under a combination of psychiatric treatment, attention to somatic needs, vitamin therapy and betterment of domestic and social adjustment.

SUMMARY AND CONCLUSIONS

Electroshock therapy is a valuable therapeutic agent in cases of involutional depressions, cyclic depressive states, reactive and late life depressions and early cases of schizophrenia. It effects recovery in about 85 per cent of patients with involutional depression and, when administered early, aborts or greatly shortens the duration of manic depressive, depressive attacks, thus aiding in reducing hospitalization time, shortening the duration of disability and preventing suicidal attempts.

It is of value in selected cases of psychoneurosis, and should be used only in resistant cases after other methods of treatment have failed to cause improvement.

The utilization of general-hospital facilities for intramural and ambulatory electroshock therapy has not only brought relief to patients who would otherwise have refused treatment because of their reluctance to enter a psychiatric hospital but also acted as a morale builder to these patients by removing the feeling of ostracism that occasionally is still associated with hospitalization in a psychiatric hospital.

It is recommended that even the smaller general hospitals have one or more rooms equipped for the treatment of acute mildly disturbed psychiatric problems offering a good prognosis and amenable to rapid treatment. Such facilities if more widely

used would eventually aid materially in relieving some of the load in overcrowded state and private psychiatric hospitals

PRESIDENTIAL ADDRESS*

DAVID W PARKER, M D †

MANCHESTER, NEW HAMPSHIRE

MANY of the senior group of this society have had the rare opportunity of observing the growth of the art and science of modern surgery from a scope that, judged by present standards, was extremely limited to its present almost unbelievable heights. This development has carried with it serious responsibilities to the surgical profession, and also grave problems in the training of prospective surgeons to cope with the highly diversified and technical procedures that it will be necessary for them to master if they are to take their place as specialists in surgery. There have also been problems of raising the standards of hospital care, expansion of laboratory facilities and refinements of record systems and the limitation of incompetent and unnecessary surgery.

Volumes have been written and published through the years by leaders in the surgical field dealing with these problems. The efforts of the American College of Surgeons and, later, of the American Board of Surgery have been of inestimable value in correcting many of the existing weak spots in the practice of surgery. However, many phases of the situation have not been and probably cannot be, reached by these bodies without a fuller program, and definitely more decisive action by organized groups of surgeons who are in a position to mold the conscience and ideals of surgeons in general in their sphere of influence — for example, the New England Surgical Society in New England.

One hesitates to speak on the training of surgeons before a group who have recently listened to the excellent papers by Lanman¹ and Harvey² on this subject. These men have admitted that the train-

ing of surgeons has become too great a load for the teaching hospitals and although many references have been made to the possibility of training surgeons in the smaller hospitals, no positive action has been taken to supplement these suggestions. After forty years of surgical practice in a smaller community, one develops some ideas on this subject, and I hope to present to you a plan and I use this word guardedly, that may eventually bring the outlying medical communities into the orbit of teaching institutions.

Until recently, there have been two schools of surgical teaching in this country: the prolonged period of carefully supervised training in teaching hospitals and clinics, and the method of trial and error used by general practitioners to perfect themselves gradually in the art of surgery. It was standard practice some years ago for a physician to begin in general practice and work into surgery gradually, and, had it not been for this self-training, much of the necessary surgery in the smaller hospitals would have gone undone. Today, such a practitioner has to ask a fully qualified surgeon to assist him in operations on appendixes, hernias and gall bladders and up the scale until he has developed enough dexterity to operate fairly safely. And all the while that the senior surgeon is keeping him out of trouble and guiding him through the maze of surgical technique and postoperative care, the novice collects the fee and poses as the surgeon. Today, such a practice is unnecessary, and all too often exploits the surgeon who is asked to assist. The American Board of Surgery and American College of Surgeons have done much to discourage this practice by listing minimal requirements of training before a physician is admitted to the surgical staff of a hospital. But the practice will not disappear until every recognized hospital adheres rigorously to these requirements.

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 1, 1945.

†Surgeon, Eliot Hospital; consultant, Exeter Hospital, Exeter, New Hampshire; consultant, Alexander-Eastman Hospital, Derry, New Hampshire.

When more and more hospitals close their doors to the surgeon of subminimal requirements, it means that the smaller hospitals are no longer instrumental in training surgeons as they have been in the past, and a correspondingly heavy load is being thrown on the large training centers. Some plan whereby the smaller medical communities can be enlisted again in the training of surgeons who measure up to the high standards that are demanded must now be evolved.

Before any plan is outlined, it must be known what sort of surgeons are to be developed. The surgeon who has completed his residency, qualified for his board examinations and then settled in a large metropolitan area will restrict his surgical practice from the outset to some special field. If he ventures to a community with a small hospital, he will naturally seek to limit himself to surgery, but he cannot be so restricted as his city brethren. He will mainly be a consultant, for patients will not normally turn to him at once, but will be referred by the general practitioners, who see the bulk of patients when they are first taken sick.

The smaller communities cannot support specialists in every field — gynecology, urology, orthopedics, abdominal surgery and so forth, nor can a surgeon expect to keep very busy if his training has been limited to abdominal surgery. From the standpoint of the general practitioner, a surgical consultant must be able to deal with a wide variety of cases if he is to be of any great value to the medical community.

This imposes on the plan of training for the general surgeon a specific obligation, which is not fully recognized, if one is to judge by present trends. More and more, cases are segregated into special services. The young surgeon in his hospital training develops into what might well be called a glorified belly artist. He can remove an appendix or gall bladder and resect a stomach or rectum, but, all too often, the female pelvic organs, the prostate gland and the broken bone are terra incognita. Only if the young surgeon is willing to spend extra years in the larger hospitals can he develop a competence in general surgical work, which the small community needs and the general practitioner demands from the consultant in surgery.

Surgical leaders would do well to insist on rotation through special services by all the young surgeons. This does not mean rotation in menial tasks — a *leitmotif* of intravenous therapy, blood counts and postoperative care — but training that develops both manual dexterity and operating poise in all the common surgical conditions. Under such a system, it would be impossible to produce a situation such as recently came to my attention: a young surgeon had qualified for the American Board of Surgery and yet had no formal training in gynecologic surgery, which comprises 30 to 60 per cent of the practice for the general surgeon in the smaller community.

What I am saying has been expressed repeatedly by leaders in the specialties such as gynecology, obstetrics, orthopedics and urology. These men openly admit that the best practitioners of their particular arts have first of all a broad training in general surgery, so that, whether a man intends to go out to a smaller hospital or remain in the larger centers, his *basic* training should be essentially the same.

The smaller medical community has often glaring deficiencies in surgical service that could well be corrected by incoming surgeons of the younger generation. Perhaps an outside consultant is called in for thoracic cases or difficult fractures or plastic surgery. If the most recent addition to the surgical department can fill any existing gap in surgical talent, his path will be so much easier, and his acceptance by the staff less restrained.

This imposes on the surgeon who contemplates a move to the smaller hospitals the duty of acquainting himself intimately with the medical talents in the community where he plans to practice. Such knowledge will stimulate him to develop special ability in some limited field in addition to his broader training.

Is it possible to fit the smaller hospital into such a program of training? One must not be too impressed by size, for the "sticks" does not so much describe a geographic location as it does a state of mind. It is well to remember that patients in the mountains of New Hampshire and in the fishing villages of Maine have exactly the same diseases as those in Providence or Hartford. Wherever a surgeon takes a careful history, does a thorough examination and makes the necessary x-ray and laboratory studies for an intelligent working diagnosis, sound medicine is practiced, and there the student of surgery can learn and be trained.

A far more delicate subject is the level at which the smaller hospital shall assist in training surgeons. A plan that seems favored by some authors on this subject is to have surgeons train as interns for two or three years in the large center and then finish their apprenticeship in the smaller hospital.

The last part of a surgical training, or the resident stage, is by far the most important. It is the great climax for which all the previous years are but a preparation. The self-confidence, poise and judgment that are essential in the private practice of surgery are developed in this final phase. Smaller hospitals, with their more limited facilities, cannot complete the surgical training nearly as well as the large institutions at the last stage. If they are to be enlisted in the training program, it should be at the level of interns and assistant residents. Any plan that seeks to send men into practice before their training is fairly complete — that is, before their residency has been served — should be discouraged.

Surgery everywhere is a highly competitive field. One reason for this is that surgical fees are propor-

tionately much higher than those in other medical fields. Few of the thousands of doctors in this country who are engaged in private practice can afford to disregard the economic component of their profession. As a corollary, there is competition on two levels in surgery—the professional and the economic. Those who have enjoyed the superior training under men with working ideals usually place the professional consideration of competence first, and these high standards pertain particularly in academic circles. Above all, there is need for a program for training surgeons who can compete with the skills taught them by emphasis on good deeds, and who can succeed so well that they can prosper economically without stooping to unethical practices. All too often the greatest stumbling block in the path of a competent young surgeon who wishes to practice according to the highest ethics is an unscrupulous older colleague who attempts to shut him out.

Such a person may be a good surgeon with a jealous disposition, but usually he is one who uses the knife consistently as a diagnostic instrument of first recourse, and deliberately blames every poor result on the patient's disease. He is willing to continue his indiscriminate surgery even though he clearly realizes his own surgical imperfections.

When such a person (or a group of such men) gains control in a medical community, the place is not favorable to the healthy development of a younger surgeon who may have an excellent training. He is restricted at the outset, every poor result is magnified, and all too often, he is driven in despair to adopt exactly the same methods as his older colleagues.

Let the leaders in the medical centers sound out their young graduates who have settled in the smaller communities, and I am certain that they will find this to be about the greatest obstacle to good surgery that the young surgeon faces.

Some solution to this problem is necessary if openings for the younger generation of surgeons are to be developed, and if the smaller hospitals are to be enlisted in the training program. Here is a problem for the trustees of the hospital. The terrible frustration of talent and training that obtains in many smaller hospitals will not be remedied unless the tactics of the vested interests are curbed by the hospital trustees.

One can expostulate on what should be and on the changes to be made, but no plan that involves the small hospitals will ever succeed without a full and active support from the trustees. Theirs is the power to set standards that will attract the best talent of the community, conversely, if they allow anyone and everyone to do surgery, they will discourage the most competent.

The hospital trustees are selected in various ways, but, by and large, they are local citizens with a record of good business ability. These men are

often fully occupied with their business duties, and the hospital is a charity service that they assume as an obligation to the community. If the bills are paid and the hospital is quiet and clean, they believe that they have discharged their duties, and that the medical profession should be grateful for a place to work. To formulate some policy regarding professional practices in the hospital, they are heavily dependent on the director, who may be a physician, a layman with business training or a nurse who has climbed up from one administrative position to another until she has arrived at that of superintendent. Unless the director or some of the trustees make a special effort to enlighten themselves on such matters as surgical standards and the development of the best practices in the hospital, the staff finds itself floundering in *status quo*.

Hospital trustees need help in the form of sound and impartial advice if they are to keep their hospital apace of new standards in surgery, and if they dare not seek it locally they should find it elsewhere in some competent consultant.

All the things that I have said are by way of formulating a plan for the training of surgeons in smaller hospitals. This purpose will be served best by an integrated plan that utilizes the smaller hospital as part of a training system. Smaller hospitals with such essential facilities as adequate x-ray equipment, a roentgenologist, laboratory facilities and a pathologist should affiliate with larger teaching hospitals. The staff of the parent hospital could serve as consultants to the smaller institutions, and also function as chiefs of service. Clinics and conferences in the teaching hospitals could be open to the staffs of the affiliated groups. By enlisting the support of the trustees for this plan, the smaller hospitals could develop such standards of personnel and practice that they could be trusted to help train interns or assistant residents in rotation from the teaching hospitals. In this way, the new generation would learn much about surgical practice in smaller communities and also find openings for themselves. The trustees might well ask the director of the central hospital to serve on a retainer-fee basis as consultant in local problems that seem difficult of solution.

In his presidential address last year, Dr Lanman¹ hesitated to suggest the formation of another committee. I do not hesitate, but boldly submit that this society choose some members to make a careful study and formulate concrete proposals that can be adopted as a general program to support. The time has come to implement words about training surgeons in smaller hospitals with a realistic and workable plan.

SALT-LOSING NEPHRITIS SIMULATING ADRENOCORTICAL INSUFFICIENCY*

Report of a Case

WILBUR H SAWYER, M D,† AND CHESTER SOLEZ, M D ‡

THORN, Koepf and Clinton,¹ in 1944, reported 2 cases of renal failure simulating adrenocortical insufficiency. They called this syndrome "salt-losing nephritis." Symptoms such as asthenia, weight loss, nausea, vomiting and hypotension were observed and attributed to an excessive loss of sodium and chloride in the urine. Such salt loss was not due to a deficiency of adrenocortical hormones but to disease of the renal tubule, the end-organ on which such hormones act in controlling the reabsorption of sodium and chloride from the glomerular filtrate. The symptoms due to the salt loss were relieved by the administration of sodium, chloride and bicarbonate. The kidneys in these cases were demonstrated to be incapable of normal responses to desoxycorticosterone acetate (DOCA), to pituitrin or to the parathyroid hormone.

The case presented below is another example of salt-losing nephritis simulating Addison's disease. The presence of tanning of the skin, asthenia, weight loss, nausea, vomiting and hypotension, and the absence of cardiac enlargement, eye-ground changes or abnormal urinary constituents led at first to the diagnosis of Addison's disease. This was practically impossible to disprove before death. The presence of severe renal tubular insufficiency, however, with an inability to reabsorb salt in response to DOCA was readily demonstrated.

CASE REPORT

E. T., a 53-year-old married shoe salesman, first entered the hospital on March 11, 1947, complaining of weakness, weight loss and frequent vomiting following meals. He gave a history of mild diurnal frequency (five or six times) and nocturia (four or five times) for several years.

Seven years before admission he had entered another hospital for treatment of a bleeding duodenal ulcer. After this he had been essentially well for about 1 year. He then started experiencing epigastric pain between meals, relieved by food or alkali. Four years before admission he again entered the same hospital, complaining of gastrointestinal bleeding. At that time the blood nonprotein nitrogen was 319 mg per 100 cc, and the urine contained albumin and white and red cells. After 1 month the nonprotein nitrogen had fallen to 92 mg per 100 cc, and he was discharged.

One year before admission he again entered that hospital complaining of epigastric distress. The nonprotein nitrogen was 125 mg per 100 cc, the urine showed a + test for albumin, and the sediment contained a few white cells. Five days later the urine was reported as completely normal. One month later the nonprotein nitrogen was 60 mg per 100 cc, and he was discharged.

Physical examination revealed a thin, pale and weak man. The body weight was 128 pounds. The eye grounds appeared normal. The chest was clear. The heart was not enlarged on physical or x-ray examination. There was some tenderness deep in the epigastrium. The skin appeared diffusely tanned. There was no pigmentation of the mucous membranes.

The blood pressure was 120/70, and the pulse 96.

Examination of the blood disclosed a red-cell count of 2,800,000, with a hemoglobin of 8.7 gm (photometric-cell technique), and a white-cell count of 10,000, with 59 per cent neutrophils. The blood Kahn reaction was negative. The nonprotein nitrogen was 159 mg, the creatinine 60 mg, the total protein 7.4 gm, and the blood chloride (as sodium chloride) 430 mg per 100 cc.

A gastrointestinal series showed an irregular duodenal cap and moderate pyloric obstruction to the passage of barium. Intravenous pyelograms disclosed no visible excretion of the diodrast. An intravenous phenolsulfonephthalein excretion test revealed a total of 10 per cent excretion of the dye in 2 hours. A urine concentration test demonstrated a maximum specific gravity of 1.010. Fifteen routine morning urine specimens showed specific gravities ranging from 1.003 to 1.012. In one specimen the sediment contained rare red cells, and in several it contained from 1 to 8 white cells per centrifuged high-power field. At no time was albumin or casts observed.

After admission the patient showed no signs of gastrointestinal bleeding. He was placed on hourly administration of milk and cream and antacids. Vomiting, however, became severe, and constant suction was begun through a Levine tube introduced into the stomach. Large quantities of dextrose and saline solutions, 1500 cc. of plasma and 500 cc. of whole blood were administered intravenously during the first 2 hospital weeks. The suction was discontinued at the end of 5 days, and vomiting did not immediately recur. About 2 weeks after admission the blood pressure was 130/72, and the nonprotein nitrogen had fallen to 60 mg and the blood creatinine to 3.2 mg per 100 cc. The white-cell count was 5800, and the hemoglobin 8.7 gm. The patient remained relatively asymptomatic and gained about 10 pounds of weight during the ensuing month. During this time he began taking about 15 gm of sodium bicarbonate daily for relief of mild epigastric distress.

Two months after admission he experienced more severe epigastric pain and repeated vomiting. He became extremely weak, the pulse became rapid, and the blood pressure fell to 80/60. He lost 12 pounds of weight in 1 week. The nonprotein nitrogen rose to 100 mg, and the creatinine to 7.5 mg per 100 cc. The blood chloride (as sodium chloride) was 429 mg per 100 cc. At this time the patient was seen by several medical consultants. The presence of diffuse tanning of the skin, nausea and vomiting, elevation of nonprotein nitrogen and creatinine, marked asthenia and weight loss led to a diagnosis of Addison's disease in crisis. The absence of known hypertension and of albumin and formed elements in the urine, the normal heart size and the normal eye grounds were all taken as indications that the patient did not have a significant degree of nephritis. Part I of the water diuresis test of Robinson, Power and Kepler² was performed and interpreted as being consistent with the diagnosis of Addison's disease. The night urinary volume was 1715 cc, and the maximum hourly urine specimen after the ingestion of water was 200 cc.

In view of the diagnosis of Addison's disease the patient was given 36 gm of sodium chloride and 30 cc of adrenocortical extract intravenously on May 21 and 22, and was started on desoxycorticosterone acetate in oil (DOCA) intramuscularly, 10 mg a day. He continued to receive 15 gm of sodium bicarbonate by mouth daily. The immediate response was dramatic (Fig 1), the blood pressure rose in 3 days to 110/68, and the patient experienced marked subjective improvement. This was interpreted as added evidence for the presence of Addison's disease. Despite the continuation of 10 mg of DOCA daily, however, as well as the 15 gm of sodium bicarbonate, the symptoms of asthenia, nausea and vomiting returned. Over the course of 10 days

the blood pressure again fell to 80/50. He was again treated with 20 cc of adrenocortical extract and 18 gm of sodium chloride given intravenously. He was also placed on 5 gm of sodium chloride in enteric-coated capsules daily in addition to the dietary salt and 15 gm of sodium bicarbonate orally. On this regime there was again a definite subjective improvement, and the blood pressure and body weight showed a more gradual but definite rise (Fig 1).

At this point it was suspected that the patient had a salt-losing nephritis as described by Thorn, Koepf and Clinton.¹ Accordingly, on June 17, DOCA was discontinued. The

the same amounts of salt and bicarbonate, to watch for the formation of edema, and to follow an intermediate ulcer diet. The diagnoses on discharge were salt-losing nephritis and duodenal ulcer, chronic, with partial obstruction.

He adjusted himself well at home on this regime but did not return to work. He followed the directions until about 4 months after discharge, when he again experienced epigastric pain and vomiting. He re-entered this hospital on December 9, after a 3-day period of hematemesis and melena. On admission he appeared very pale and weak. The body weight was 128 pounds. The blood urea nitrogen was only 37 mg, the

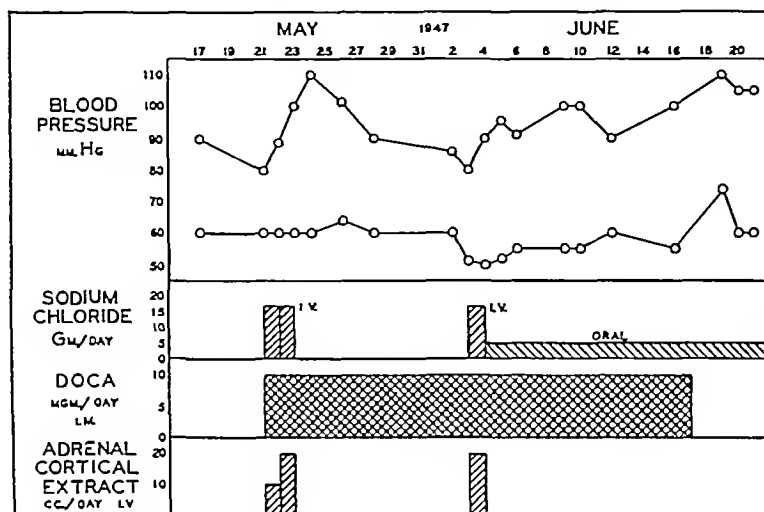

FIGURE 1 Ineffectiveness of Desoxycorticosterone Acetate in Oil (DOCA), 10 mg Intramuscularly Daily, in Maintaining the Blood Pressure of a Patient with Salt-Losing Nephritis

patient continued to show a steady rise in blood pressure, body weight and feeling of well-being on sodium chloride and sodium bicarbonate given orally alone.

Since a patient with adrenal insufficiency alone might show similar improvement on this therapy an attempt was made to determine whether the kidney itself was unable to respond to the administration of DOCA. Urinary and blood chloride determinations, blood pressure and body weight were followed before, during and after the administration of a large daily dose (20 mg) of DOCA for 7 days. The diet was kept constant during this period, and the patient continued to take 5 gm of sodium chloride and 15 gm of sodium bicarbonate orally. The results obtained are shown diagrammatically in Fig 2. It appears that gains in body weight and blood pressure during this observation period, including the time before and after DOCA was administered, were quite steady and not greatly influenced by the administration of the drug. There was only a slight decrease in the concentration of urinary chloride from 650 to 600 mg per 100 cc (as sodium chloride) during the administration of DOCA, and the blood chloride level was not greatly altered.

A pituitrin concentration test, consisting of 10 units of pituitrin given subcutaneously, was performed, and the urine collected at one and two hours. The specific gravities of the specimens were 1.009 and 1.008 respectively. An intravenous glucose tolerance test was also performed, 0.5 gm of glucose per kilogram of body weight being given intravenously over a 30-minute period. Blood glucose levels were as follows: fasting control 111 mg, 1 hour 167 mg, 2 hours 114 mg, 3 hours 87 mg, and 4 hours 83 mg per 100 cc.

The patient continued to feel well on 5 gm of salt and 15 gm of sodium bicarbonate by mouth daily. The blood urea nitrogen was relatively stable at between 35 and 45 mg per 100 cc. The carbon dioxide combining power ranged between 55 and 65 vol per cent. The weight reached 127 pounds. He was discharged on August 23, with advice to continue taking

creatinine 2.7 mg, and the blood chloride (as sodium chloride) 483 mg per 100 cc. The urinary specific gravity was 1.007, and no formed elements or albumin was present. Repeated blood transfusions were given, but signs of slow bleeding continued. On December 26 a subtotal gastrectomy was performed as an emergency procedure. After operation the patient developed clinical and roentgenologic signs of pulmonary edema. The blood nonprotein nitrogen was 150 mg per 100 cc, and the red-cell count 4,200,000. Despite oxygen, morphine, digitoxin and penicillin the signs of pulmonary congestion increased, and early on the morning of December 28, he had a single clonic convulsion and died. At autopsy* there was a fresh midline upper abdominal scar. The skin was a diffuse light brown.

The pleural cavities contained about 550 cc of pink fluid. The peritoneal cavity contained 100 cc of red fluid. There was a recent gastric resection, and gastrojejunostomy. These anastomoses were firm and healing in good position. The duodenal stump was closed and covered with omentum.

The right lung weighed 1100 and the left 850 gm. They were firm and boggy in consistence. On section there was a tremendous amount of foamy pink fluid from all lobes and in the major bronchi.

The heart weighed 380 gm. There was dilatation of the right ventricle, and the coronary arteries were extensively calcified. There was moderate narrowing, but no occlusion of the vessels.

There were two ulcers in the duodenal stump. The remainder of the intestinal tract was normal except for large amounts of black fecal matter.

The liver weighed 2050 and the spleen 300 gm. Both showed chronic passive congestion.

The pancreas weighed 100 gm, the head was firm, and the body and tail were normal in color and consistence.

*Performed by Dr. Russell H. Pope.

The adrenal glands were greatly increased in size. The left weighed 21 gm. The right was torn during removal and could not be weighed but appeared similar in size to the left. The cortex was normal in color and about twice the normal width.

The kidneys were small, weighing 70 gm each. The capsules stripped with difficulty. The surface was finely granular. The organs cut with increased resistance to the knife. The cortex was reduced in width, being about 3 mm thick. The boundaries between cortex and medulla were indistinct. The pyramids were small but not flattened. The pelvic mucosa

appreciable intimal disease. There were numerous cystic spaces surrounded by a heavy layer of pink-staining acellular material containing a blue-staining substance resembling calcium. These were located for the most part in the connective-tissue septums.

The kidneys, on multiple sections, demonstrated remarkably few functioning glomeruli. Nearly all were represented by hyaline balls, some of which showed blue-staining calcific precipitates. Occasional glomeruli appeared to be functioning, but even these revealed separation of the tufts, adhesions and marked thickening of Bowman's capsule. A

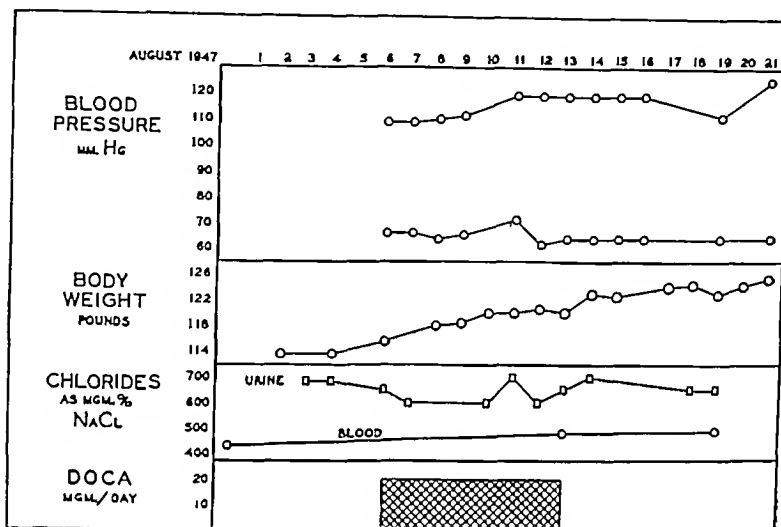

FIGURE 2 Ineffectiveness of Desoxycorticosterone Acetate in Oil (DOCA), 20 mg Intramuscularly Daily, in Significantly Altering the Blood Pressure, Body Weight and Urinary Excretion of Chloride in a Patient with Salt-Losing Nephritis

was smooth and white except for a few small petechial hemorrhages. The ureters, bladder and prostate appeared normal. The thyroid and parathyroid glands, brain and spinal cord were not examined.

Microscopical examination of the lungs showed moderate dilatation of the alveoli. The alveolar septums were thickened in many areas, with definitely increased connective tissue. The ends of the septums were clubbed and contained round, dark-blue granules surrounded by dark-blue rings suggestive of calcium. Streaks of granular, dark-blue material were seen along some of the septums. Near the hilar region these granules were quite numerous and in places had been shed into the alveolar spaces. In these areas the alveolar walls appeared quite stiff and thickened, and calcific rings were apparent in the septums, sometimes surrounding an entire alveolus. Some of the smaller vessels showed extensive calcific deposits in the media. A rare foreign-body giant cell was seen surrounding the calcific granules. Many of the alveoli were filled with protein precipitates and comprised many large macrophages containing dark pigment. The vessels of the lung were greatly dilated.

The heart revealed definite hypertrophy of the muscle fibers, the interstitial spaces appeared swollen and vacuolated. The smaller arteries demonstrated slight calcific changes in the media. There were early calcific deposits at the base of the aortic valve. The coronary arteries showed only slight fibrous thickening of the intima without cholesterol deposits. The media just below the internal elastic membrane was completely replaced in a ring-like manner by heavy deposits of calcium, which were strictly limited to the media. This calcification extended from the ostia into the smallest arterioles.

The liver and spleen disclosed chronic passive congestion. The larger vessels running through the parenchyma of the pancreas showed marked medial calcification without

few disclosed partial hyalinization. The renal parenchyma was greatly altered by an increase in connective tissue and areas of round cells. Many of the tubules were atrophied, and the epithelial cells were small, clumped together and surrounded by a remarkably thickened basement membrane. In a few places this membrane took a dark-blue stain suggesting calcium. The calcification of the basement membrane was quite striking and was seen on all the sections. There were extensive calcium deposits of another type in every field. These consisted of a great number of dark-staining granules clumped together to form irregular masses. The pyramids were extensively calcified in this manner, and some of the hypertrophied tubules were filled with these calcific balls but for the most part they seemed to be in the interstitial spaces. The larger arteries showed a severe degree of medial calcification. The veins were distended. The entire parenchyma was much reduced in width. The pelvic and ureteral epithelium was normal.

The adrenal glands demonstrated a diffuse increase in the cortical area and several small hyperplastic nodules or adenomas. The cortex appeared twice as thick as normal. The medullary cells were normal except for moderate atrophy.

Sections of bone taken from the sternum revealed no noticeable changes in the bony trabeculae or marrow.

DISCUSSION

The post-mortem studies corroborated the diagnoses of chronic duodenal ulcer and renal disease without Addison's disease. The most interesting findings were the extensive deposits of calcium in the lungs, kidneys and pancreas and in

the media of the arteries, including the coronary arteries. The medial calcification could not be considered ordinary arteriosclerosis because of the definite lack of intimal changes in the larger arteries. It seemed to be a special form of calcification resembling Mönckeberg's sclerosis or senile arteriosclerosis. It has been described as due to calcinosis from various causes. The calcification in this case was not extensive enough to be considered calcinosis but falls into the group of cases with "metastatic calcification."³ Most of these patients were emaciated with severe disease of the bones, but the patient in the case reported above had no bone disease. Similar lesions can be produced in animals with excessive doses of vitamin D, chronic alkalosis and hypochloremia.⁴ The calcification of the tubular basement membrane in this case suggested a specific disease of the tubules in view of the presence of salt-losing nephritis. The extensive deposits of calcium in other tissues pointed to a more general metabolic dyscrasia. The cause of this was open to speculation. This dyscrasia may have been associated with the large amount of alkali consumed by the patient over a long period. The interstitial calcification of the kidneys is a common finding in chronic renal disease and undoubtedly resulted, at least in part, from local increased alkalinity of the renal tissues.

The cause of death was probably pulmonary edema and cardiac edema and dilatation due to an overloaded circulation following multiple transfusions for the shock of operation and the prolonged gastrointestinal hemorrhage.

This case bore a striking resemblance in many respects to the 2 reported by Thorn, Koepf and Clinton.¹ Only once during the last two periods of hospitalization did the patient show abnormal formed elements in the urine, and examination never disclosed albuminuria. Formed elements were notably absent in the urine in both the cases reported by Thorn, Koepf and Clinton. Other findings in common were hypotension, normal heart size, normal eye grounds, weight loss, nausea and vomiting. A slight or absent response to DOCA and a satisfactory response to salt alone were also striking in these cases. The age of the patient, however, was fifty-three when first seen here. Both patients of Thorn et al were twenty-one at the time of onset.

Both their patients entered a terminal stage consisting of edema, hypertension, nitrogen retention and cardiac failure. Death in the case presented above was precipitated by acute severe gastrointestinal hemorrhage, the emergency operation and multiple transfusions. Pulmonary edema appeared and was probably responsible for death. This terminal picture was not allowed to develop naturally as in the 2 cases of Thorn et al.

Our case was complicated by the presence of chronic duodenal obstruction. This undoubtedly

contributed greatly to the salt loss, particularly the chloride loss. During one period of severe protracted vomiting and hypotension, however, the patient maintained a daily urinary chloride excretion of over 18 gm (as sodium chloride) and a daily urine volume of over 3 liters. This should have demonstrated that his kidneys were unable to retain chlorides and water at a time when they were most desperately needed to maintain the chemical equilibrium. A similar picture may be seen in adrenal insufficiency when there is moderate salt loss from vomiting, diarrhea, fever or excessive sweating. Here again the kidneys are unable to retain salt in the absence of adrenocortical hormones, the electrolyte balance suffers, and Addisonian crisis may ensue.⁵

The pathological picture of the kidneys in the cases reported by Thorn, Koepf and Clinton¹ could not be called specific. The authors concluded that salt-losing nephritis occurred late in the course of slowly progressive kidney disease. Their cases showed extensive scarring, hypertrophy of the remaining glomeruli, and dilatation of the tubules.¹ The findings in the kidneys in our case were consistent with a severe chronic glomerulonephritis, and nothing that could be interpreted as being a specific tubular lesion was demonstrated.

Instead of atrophy or absence of the adrenal glands, autopsy revealed a fairly marked hyperplasia of the adrenal cortex. It is of interest to note that 1 case of Thorn, Koepf and Clinton also showed definite hypertrophy of the adrenal cortex, although the authors did not comment on this fact. One may speculate that since hypertrophy of the adrenal cortex was present in 2 out of 3 reported cases of salt-losing nephritis the cause of such hypertrophy is the salt loss itself. Such hypertrophy may represent an attempt on the part of the adrenal cortex to stimulate the renal tubules to retain salt and compensate for the excessive salt loss.

It is not known whether a low blood sodium or chloride can stimulate the adrenal cortex.⁶ There were undoubtedly other adequate causes for adrenal hypertrophy in this case, but this remains a possibility. A rough parallel might be drawn between such a hypothetical mechanism and the known mechanism of parathyroid hypertrophy in cases in which there is an excessive loss of calcium ion in the urine. Albright et al⁷ have shown that the stimulus to parathyroid hypertrophy in such cases is the depression of blood calcium concentration.

In chronic renal insufficiency significant salt loss is not rare.^{8,9} Its recognition may be very important in cases that show neither edema nor hypertension. When such salt loss exists it contributes to the retention of nitrogenous substances in the blood. The depletion of salt in the body fluids decreases the rate of glomerular filtration probably by reducing the renal blood flow.¹⁰ In such cases the salt loss may be easily replaced by the cautious

Both their patients entered a terminal stage consisting of edema, hypertension, nitrogen retention and cardiac failure. Death in the case presented above was precipitated by acute severe gastrointestinal hemorrhage, the emergency operation and multiple transfusions. Pulmonary edema appeared and was probably responsible for death. This terminal picture was not allowed to develop naturally as in the 2 cases of Thorn et al.

Our case was complicated by the presence of chronic duodenal obstruction. This undoubtedly

contributed greatly to the salt loss, particularly the chloride loss. During one period of severe protracted vomiting and hypotension, however, the patient maintained a daily urinary chloride excretion of over 18 gm (as sodium chloride) and a daily urine volume of over 3 liters. This should have demonstrated that his kidneys were unable to retain chlorides and water at a time when they were most desperately needed to maintain the chemical equilibrium. A similar picture may be seen in adrenal insufficiency when there is moderate salt loss from vomiting, diarrhea, fever or excessive sweating. Here again the kidneys are unable to retain salt in the absence of adrenocortical hormones, the electrolyte balance suffers, and Addisonian crisis may ensue.⁵

The pathological picture of the kidneys in the cases reported by Thorn, Koepf and Clinton¹ could not be called specific. The authors concluded that salt-losing nephritis occurred late in the course of slowly progressive kidney disease. Their cases showed extensive scarring, hypertrophy of the remaining glomeruli, and dilatation of the tubules.¹ The findings in the kidneys in our case were consistent with a severe chronic glomerulonephritis, and nothing that could be interpreted as being a specific tubular lesion was demonstrated.

Instead of atrophy or absence of the adrenal glands, autopsy revealed a fairly marked hyperplasia of the adrenal cortex. It is of interest to note that 1 case of Thorn, Koepf and Clinton also showed definite hypertrophy of the adrenal cortex, although the authors did not comment on this fact. One may speculate that since hypertrophy of the adrenal cortex was present in 2 out of 3 reported cases of salt-losing nephritis the cause of such hypertrophy is the salt loss itself. Such hypertrophy may represent an attempt on the part of the adrenal cortex to stimulate the renal tubules to retain salt and compensate for the excessive salt loss.

It is not known whether a low blood sodium or chloride can stimulate the adrenal cortex.⁶ There were undoubtedly other adequate causes for adrenal hypertrophy in this case, but this remains a possibility. A rough parallel might be drawn between such a hypothetical mechanism and the known mechanism of parathyroid hypertrophy in cases in which there is an excessive loss of calcium ion in the urine. Albright et al.⁷ have shown that the stimulus to parathyroid hypertrophy in such cases is the depression of blood calcium concentration.

In chronic renal insufficiency significant salt loss is not rare.^{8,9} Its recognition may be very important in cases that show neither edema nor hypertension. When such salt loss exists it contributes to the retention of nitrogenous substances in the blood. The depletion of salt in the body fluids decreases the rate of glomerular filtration probably by reducing the renal blood flow.¹⁰ In such cases the salt loss may be easily replaced by the cautious

addition of extra salt to the diet. This in turn produces a decrease in nitrogen retention. Since the concentration of salt in the urine may be relatively fixed, variation in the urinary volume causes a proportional variation in the total salt excretion. Thus, forcing of fluids may make the salt loss more marked unless additional salt intake compensates for this loss.⁸

Salt loss of sufficient magnitude to cause symptoms simulating adrenocortical insufficiency, however, is probably quite rare.¹ It is important that it be recognized since the response to added sodium chloride and bicarbonate may be quite gratifying. Even with a reasonable suspicion of the presence of such a condition it may be very difficult to rule out the possibility of a combination of both renal and adrenocortical insufficiencies. This can best be illustrated by our experience in the case presented above. Many procedures of use in the diagnosis of Addison's disease were unreliable in the presence of advanced renal insufficiency of this type.

Hypoglycemia is common in Addison's disease and should not be influenced by renal failure. Our patient had no hypoglycemia and had a relatively normal intravenous glucose tolerance test. This indicates that there was no profound disturbance of carbohydrate metabolism and that normal adrenal glands were present.

Urea and creatinine retention decreased by the administration of salt may occur in either adrenal or renal insufficiency. The high degree of retention and its persistence despite vigorous therapy were strong indications that a considerable degree of renal insufficiency was present.

The water diuresis test² was positive for Addison's disease in our case. This was to be expected since this test depends on the ability of the kidney to vary the volume of urine and to excrete urea and retain chloride. The functions of the kidney may be impaired in both conditions, and this test was of little or no value in distinguishing this type of renal failure from Addison's disease.^{11, 12} A salt-deprivation test¹³ might also be expected to yield a positive result in the presence of marked renal salt loss.

Urinary 17-ketosteroid excretion¹⁴ or the urinary output of cortical hormones¹⁵ should be reduced in adrenocortical insufficiency. A low urinary excretion of 17-ketosteroids would have been of little help in itself. This may occur in chronic debilitating diseases even in the presence of anatomically normal adrenal glands.¹⁶ This was true in 1 of the cases of salt-losing nephritis reported by Thorn, Koepf and Clinton.¹ If a normal value had been found in our case it would have been of great help in establishing the proper diagnosis. Unfortunately, laboratory facilities for such assays were not immediately available to us.

Also valuable would have been the determination of eosinophile response to the pituitary adrenocorticotrophic hormone.¹⁷ A normal fall in eosinophil count following the administration of this hormone would have been strong evidence for the presence of an intact adrenal cortex. The necessary material, however, was not available to us.

Of prime importance in the establishment of the renal basis for the excessive salt loss in this patient was the lack of a normal response to the administration of DOCA. We observed that large daily doses of the drug did not maintain the patient (Fig. 1) or substantially alter the concentration of chloride in the urine, the blood pressure or the body weight (Fig. 2). Such doses of DOCA should exert a striking effect on the reabsorption of sodium and chloride by the intact renal tubule. In a patient with normal kidneys, with or without normal adrenocortical function, this should manifest itself by a marked reduction in the renal excretion of chloride.^{18, 19}

The loss of salt in this type of renal insufficiency may be compared to the more common loss of water. Polyuria, with the excretion of large volumes of urine of low specific gravity, is a frequent symptom of renal insufficiency. This probably represents in part an inability of the renal tubules to reabsorb normal amounts of water. In these respects it resembles the polyuria of diabetes insipidus. Such polyuria, however, is not influenced by the injection of large amounts of the antidiuretic hormone of the pituitary body. It thus represents disease of the end-organ, the renal tubule, simulating disease of the posterior lobe. In salt-losing nephritis the diseased tubule is unable to respond to the influence of DOCA or natural adrenocortical hormones. This again is disease of the same end-organ simulating disease of another endocrine organ—in this case, the adrenal cortex.

Manifestations of the tubular inability to reabsorb water as well as salt were present in our case. Polyuria with the excretion of over 3 liters a day of urine of low specific gravity persisted even during periods of severe dehydration. The specific gravity did not rise after the administration of pituitrin.

This case is presented to point out at least one condition in which *excessive loss* of vital substance in the urine was of primary clinical importance in renal insufficiency. It is more usual to think of renal failure in terms of *retention* of nitrogenous products, electrolytes and water. It is important to recognize the stages of renal insufficiency in which the loss of ability to reabsorb a given solute is significant. The substances that may be lost to an important degree in renal diseases are water, sodium, chloride,^{8, 9} calcium,⁷ phosphate, amino acids and glucose.²⁰ Recognition of any such loss makes replacement therapy possible and may lead to the partial rehabilitation of the patient. This was well illustrated by our case, in which compen-

sation for the excessive urinary loss of sodium and chloride led to at least temporary relief from the most pressing symptoms

SUMMARY

A case of salt-losing nephritis simulating adrenocortical insufficiency, with the pathological findings, is presented

The difficulties of differential diagnosis and the importance of recognition and proper treatment are discussed

TRIMETON, A NEW ANTIHISTAMINIC DRUG*

A Clinical Evaluation

IRVING W. SCHILLER, M.D.,† AND FRANCIS C. LOWELL, M.D.‡

BOSTON

THOUGH the evidence is still very indirect that histamine is responsible for the allergic reaction,^{1, 2} the effectiveness of the antihistaminic drugs in the symptomatic control of hay fever, urticaria and certain cases of perennial allergic rhinitis is well recognized. On the other hand, the value of these drugs in bronchial asthma, allergic dermatoses and drug allergy is questionable. The reason for lack of benefit in these conditions is not clear. The experience with pyribenzamine ointment in the treatment of skin conditions suggests that higher concentrations at the involved site are an important factor. Furthermore, in studies in this laboratory, it has been found that whereas small doses of pyribenzamine injected intravenously may have negligible influence on induced asthmatic attacks,³ much larger doses often give short-lived protection.⁴ These experiments employing larger

doses are limited, however, by undesirable side reactions. Also, recent studies have called attention to certain other pharmacologic effects of these drugs,⁵ not specifically referable to histamine antagonism. It appears, therefore, that a search for highly specific antihistamines with low toxicity is well warranted. In an effort to obtain these agents, a number of new synthetic compounds have been offered for clinical trial, among which are the substituted pyridylalkylaminoalkanes. One of these compounds, 1-phenyl-1-(2-pyridyl)-3-dimethylaminopropane (trimeton),§ has been shown in animal experiments to possess a high degree of antihistaminic activity and low toxicity.^{6, 7} Its structural formula is shown in Figure 1. The purpose of this paper is to report on the efficacy of this drug in certain allergic disorders.

Trimeton tablets for oral administration were given to 84 allergic patients ranging in age from five to sixty years. These patients, who were about equally divided with respect to sex, had received serial injections of allergenic extracts, and offending allergens had been eliminated so far as possible

All patients were exhibiting symptoms at the time trimeton therapy was instituted. The drug was given in doses of 25 mg to 125 mg a day, and all patients were observed for several weeks and instructed to report in detail all subjective symptoms. In some cases, placebo controls were used. Relief of symptoms, when it occurred, was usually noted thirty minutes after a tablet was taken, and relief often lasted, with certain exceptions, for three or

more hours. The side effects were chiefly drowsiness (6 cases, or 7 per cent) and dryness of the mouth (3 cases, or 3 per cent). Nervousness, restlessness, nausea, dizziness or diarrhea was not noted, and weakness occurred in only 1 case (1 per cent).

DISCUSSION

From these limited clinical observations, trimeton appears to be highly satisfactory in the symptomatic treatment of hay fever, urticaria and perennial allergic rhinitis. Trimeton compared favorably with pyribenzamine and benadryl in all respects and is distinctly superior to them in its effect in perennial allergic rhinitis. Experience in this clinic with the latter compounds in the treatment of perennial allergic rhinitis has been disappointing and not in accord with the reports of other investigators. In a number of cases we had the opportunity of prescribing trimeton after pyribenzamine and benadryl had failed to give relief, and frequently trimeton was strikingly effective. In the 55 cases of perennial allergic rhinitis treated with trimeton, there were only 8 (14 per cent) who obtained no relief. Though the number of cases studied was small and treatment with allergenic extracts had been given, the figure of 85 per cent satisfactorily treated patients is impressive.

Trimeton was particularly valuable for its low incidence of side reactions. These were mild and were experienced by only 11 per cent of the patients. Dryness of the mouth and drowsiness were the chief side effects, and such reactions as restlessness, nervousness, nausea and dizziness, found in some of the other commonly employed antihistaminic drugs, were notably absent.

SUMMARY

Trimeton, a new antihistaminic drug, was clinically evaluated in 84 patients with hay fever, urticaria and perennial allergic rhinitis. Because of the favorable therapeutic response, the drug gives promise of being a valuable addition to the growing group of histamine-antagonizing compounds.

Trimeton compares favorably with pyribenzamine and benadryl in the management of certain allergic conditions and appears to be particularly effective in the symptomatic treatment of perennial allergic rhinitis.

The side reactions, occurring in only 10 of 84 patients, were mild.

more hours. Withdrawal of the drug was usually followed by a return of the symptoms.

Table 1 presents the results. Twelve patients with urticaria reported satisfactory relief of symptoms. Of 55 patients with perennial allergic rhinitis 47 (85 per cent) reported satisfactory or partial relief. Three of these patients were recorded as having obtained partial relief but actually were benefited satisfactorily for "about half an hour." Increasing the dose of the drug in these cases seemed to make very little difference in prolonging relief. Of 15 patients with hay fever 13 (86 per cent) reported satisfactory or partial relief. One patient

TABLE 1 Therapeutic Response to Trimeton

DIAGNOSIS	TOTAL CASES	SATISFACTORY RELIEF	PARTIAL RELIEF	NO RELIEF
		NO OF CASES	NO OF CASES	NO OF CASES
Hay fever	15	10	3	2
Allergic rhinitis, perennial	55	33	14	8
Urticaria	12	12	—	—
Vernal catarrh	1	—	—	1
Atopic dermatitis	1	—	—	1
Totals	84	55	17	12

with vernal catarrh who had many positive reactions to pollens and a patient with atopic dermatitis failed to obtain symptomatic relief.

Of the 84 patients, 74 (88 per cent) were completely free from any undesirable side reactions. The reactions noted in the remaining 10 (11 per cent) were mild, and, in general, could be controlled by a decrease in the dose of the drug. However, in most cases, this resulted in some loss of clinical effective-

MEDICAL PROGRESS

NEUROLOGY

WILLIAM K. JORDAN, M.D.,* AND H. HOUSTON MERRITT, M.D.†

CLEVELAND AND NEW YORK CITY

DURING the past year significant advances have taken place in many phases of neurology. Increased understanding of the physiology of the cerebral cortex has come from research into the sensory and motor organization of the neopallium of primate brains. New drugs of value in treating myasthenia gravis and states of increased muscular tone have been introduced and more information concerning the use of antibiotics in treatment of infections of the central nervous system has accumulated. These and other studies are discussed under the following headings: biochemistry, physiology and anatomy, pharmacology, infections, cerebrovascular system, convulsive disorders, myasthenia gravis and familial periodic paralysis, multiple sclerosis, and miscellaneous.

BIOCHEMISTRY, PHYSIOLOGY AND ANATOMY

Woolsey and Hines participated in a symposium on the organization of the primate cerebral cortex, which was held under the sponsorship of the American Physiological Society in 1947. In his discussion at the symposium Woolsey¹ summarized new work on patterns of sensory representation in the cerebral cortex. Until recently each of the principal cortical afferent systems was assumed to constitute a main pathway into the cortex and to be singly represented therein. However, in a series of experiments employing the evoked potential technique, Woolsey has shown that touch, vision and hearing, at least, are doubly represented in each hemisphere.

In her comments on motor organization of the cortex, Hines¹ emphasized that in subhuman primates the frontal lobe has acquired almost complete control of movement. In particular, the anterior division of the precentral motor cortex has assumed the activation of the least stereotyped varieties of extrapyramidal action and also, that aspect of control of inhibitory action against tone which is unassociated with the pyramidal system. She also pointed out that the posterior division of the precentral motor cortex has a basic organization characterized by localization of both motor activity and inhibitory action against tone. These localized activities are dependent upon the

integrity of the corticospinal system. In addition to this discrete organization of skeletal muscle control, there exists, in the same cortical field, a mass organization that survives pyramidal section and is capable of producing not only nonlocalized motor action but also nonlocalized inhibitory action against tone. Both these systems play their part in the control of movements. Under no known experimental conditions can the electric stimulation of extrapyramidal motor fields yield localized contraction of skeletal musculature. Indeed, Hines states it is the discrete organization of skeletal muscle that distinguished area 4 or the precentral gyrus from all the remaining motor fields of the neopallium of the primate cerebral cortex.

Recent work by Sugar, Chusid and French² has afforded further proof that double representation of function in the cortex is not limited to sensation. These workers have described a second motor cortex in the monkey (*Macaca mulatta*), lying on the lateral (exposed) and medial (buried) walls of the frontoparietal operculum, and in the posterior portion of the insula. The arrangement of representation of body parts in this area corresponds roughly to that present in the second sensory cortex of the monkey which is posterior to this newly described motor area, and slightly overlaps it. The movements elicited from the second cortical motor area were isolated and contralateral.

Evidence that cortical organization is primarily vertical rather than horizontal has been found by Sperry.³ This investigator crisscrossed the cortex with a knife penetrating through into the white matter, and found that no impairment of motor function or sensorimotor integration is evident after an interval of a month.

Ward McCulloch and Magoun⁴ have announced that a resting tremor, abolished by movement, has been produced in monkeys by destruction of a small area in the midbrain and pontile tegmentum without injury to the corpus striatum, subthalamus or substantia nigra.

Further evidence for localization in the cerebellum has been introduced. Nims and Nulsen⁵ have found that in cats each muscular contraction elicited from the cerebral cortex can be inhibited by stimulation of a topical area of the cerebellum with precise localization.

*Research fellow in psychiatry, Western Reserve Medical School, Cleveland; assistant physician, Division of Psychiatry, Lakeside Hospital, Cleveland.

†Professor of neurology, College of Physicians and Surgeons, Columbia University; director of the Service of Neurology, New York Neurological Institute, Presbyterian Hospital, New York City.

In an important monograph recently published, Lorente de N^o has detailed the results of a decade of research into the physiology of nerve. It is impossible to summarize the many contributions described in his monograph, which will be consulted by everyone interested in this field of investigation. Among other findings, Lorente de N^o has adduced evidence that the membrane potential of a resting nerve is maintained by some component of its oxidative metabolism, rather than by diffusion potentials or Donnan equilibria resulting from the distribution of cations and anions across the cell membrane.

Hydén⁷ has described the results of cytochemical experiments on nerve cells in which the ultraviolet spectrophotometric technique developed in Caspersson's laboratory were utilized. Nucleotides and certain proteins have convenient absorption ranges for study with these procedures. Hydén has found that, in the course of intense muscular work, there is a sharp decrease in the content of protein and nucleic acids in the cytoplasm of anterior-horn cells. Acoustic stimulation of guinea pigs with tones of various frequencies and intensities produces extensive cytochemical changes in the nerve cells of the cochlear ganglion. After exposure to a tone of a frequency of 6000 cycles per second, and intensity of 80 decibels, for three hours, the ganglion cells pass through a cycle of changes, with decreases in nucleotide and protein concentrations, which reach a maximum in the second week after stimulation. Concentration levels of protein and nucleotide are restored to those of nonstimulated controls within the third week after stimulation. Electroaudiogram studies done on the stimulated animals showed no decrease of auditory functions below those of nonstimulated animals, in the period after stimulation during which cochlear ganglion-cell protein and nucleotide concentrations were decreased.

Hydén⁷ has also found that the neurones of patients suffering from long-standing manic-depressive and schizophrenic psychoses have lower protein and nucleotide contents than those of controls. Treatment of patients with these psychoses by means of malonitrile, considered a precursor of certain nucleotides, is reported to produce varying degrees of beneficial psychic stimulation. It is understood that certain issues involved in these observations on psychotic patients are not yet entirely clarified.

De Robertis and Schmitt⁸ have described the presence of tubular structures in invertebrate and vertebrate nerve preparations studied with the electron microscope. They consider these to be located intraneuronally and to be of possible significance in neural conduction.

A change in the quality of pain sensation is present in a number of clinical conditions in which there has been injury to, or disease of, the central

or peripheral nervous system. In a study of the anatomic basis for alterations in quality of pain sensibility, Weddell and his collaborators⁹ have studied the histologic appearance of areas of skin in the territory of recovering nerve lesions, and of scar tissue from cutaneous scars, in a total of 59 patients, and have correlated their anatomic findings with the results of sensory stimulation. They found that in every case in which an unusually unpleasant quality of pain could be elicited by means of a needle prick, the underlying nerve terminals subserving pain were isolated from their neighbors and no overlapping of terminals was present. Conversely, in no case in which this isolation was not found microscopically, could pain of unpleasant quality be produced. It was also found that alterations in the quality of pain sensibility were not correlated with the presence of morphologically abnormal pain endings. Such endings, however, were associated with disturbances of the threshold of pain sensibility.

This pattern of innervation found in areas of abnormal sensation offers marked contrast with that of normal skin, which has been extensively investigated by Weddell¹⁰. He has found that in normal skin the network of nerve endings subserving the sensation of pain is disposed in such a manner that any one area of skin is supplied by several overlapping terminals derived from different axons.

Thus, these investigators conclude that the occurrence of "over-reaction" to painful stimuli in various clinical conditions is caused by a "reduction in the normal pattern of impulses presented to consciousness," and present the hypothesis that abnormal sensation of pain in association with central disturbances—for example, in the "thalamic syndrome"—is associated with a "reduction in pattern" through damage to particular central nervous pathways.

Feindel et al¹¹ have introduced the use of methylene blue injected into an experimental subject before death as a method of staining nervous tissues *in vivo*.

PHARMACOLOGY

In the course of an investigation into the pharmacology of glycerol ethers, Berger and Bradley¹² made the observation that a beta-dihydroxy-gamma-(2-methylphenoxy)-propane, subsequently named "myanesin," causes a transient relaxation and paralysis of certain skeletal muscles in dosages that do not affect the diaphragm and intercostal muscles, blood pressure or state of consciousness. This drug has been taken up quickly by clinicians, and is reported as useful in producing relaxation during light anesthesia,¹³ in spastic conditions,¹² in diminishing parkinsonian tremor and thalamic pain states¹⁴ and in halting jacksonian seizures.¹⁵

Early reports on myanesin¹⁵ stressed the fact that limitations to usefulness of the drug lie in its inefficacy after oral administration and in its evanescent action intravenously. However, a recent report by Berger and Schwartz¹⁶ maintains that in proper dosages and preparations the drug is effective orally in many patients, and that a more or less constant action can be achieved by repeated administrations. These investigators give myanesin in a 33 per cent (weight in volume) solution in 20 per cent (volume in volume) aqueous propylene glycol, with syrup of cherry 20 per cent (volume in volume) to improve taste of the mixture. The usual dose employed by Berger and Schwartz is 30 cc of this mixture, which contains 1 gm of myanesin. The medication is repeated as necessary, in some cases Berger and Schwartz have given it as many as five times daily. Although myanesin apparently has a low toxicity and wide margin of safety¹² the drug is not without serious side effects. One death has been attributed to the compound¹⁷. Wilson and Gordon¹⁸ report that red-cell fragility is increased, and that there is demonstrable hemolysis in the blood stream of children given myanesin intravenously. On the other hand, Berger and Schwartz¹⁶ state that after oral administration there is no hemolysis. However, they warn of the possibility of as yet undemonstrated toxic effects of myanesin in patients who receive the drug over a long period.

The mode of action of myanesin is not yet clear. Stephen and Chandy¹⁴ have reported that the drug has no action on the transmission of nervous impulses along nerve trunks, across myoneural junctions or on synapses involved in spinal reflexes. Mallinson¹³ has pointed out that it differs in its mode of action from that of curare not only in an absence of effect on myoneural junctions but also in inducing relaxation of abdominal muscles without concomitant intercostal paralysis. Hunter and Waterfall¹⁵ have stated that myanesin when given into an antecubital vein to several patients stopped jacksonian seizures in thirty seconds, an interval slightly in excess of the time they have established as arm-brain circulation time. They consider this to be presumptive evidence for a central action of myanesin, in view of Stephen and Chandy's¹⁴ demonstration of the absence of a more peripheral effect.

Parapanit, a drug employed in Europe in the production of relaxation of skeletal muscle, has been reported as not acting through the myoneural juncture.¹⁹

Telfer²⁰ has stated that the use of BAL in lead poisoning gives encouraging results, and reports of its use in arsenical intoxications have appeared.²¹

Wollenberger²² has reported that the cardiac glycoside ouabain, in low concentrations, increases the oxygen uptake of guinea-pig cortex slices, in

the presence of glucose, pyruvate or lactate. In higher concentrations, an initial increase of respiration of the cortical slices is followed by a depression. However, Wollenberger found that the glycoside has no effect on the respiratory activity of homogenized brain tissue or of isolated oxidative enzymes. He has concluded that ouabain does not directly affect the catalytic function of respiratory enzymes, but that its influence on respiration of brain slices is dependent upon the integrity of cellular structures, the site of action of the drug presumably being at the cell surface. The increase in cell respiration is perhaps due, at least partially, to facilitation of entry of exogenous substrate into the cell, the subsequent depression of respiration resulting from the loss of one or more diffusible respiration catalysts.

In connection with Wollenberger's observations, it is interesting to note that Gold et al²³ have reported that ouabain as well as several other digitalis glycosides, produces convulsions in rats.

CEREBROVASCULAR SYSTEM

A complete report by Kety and Schmidt²⁴ has appeared on the nitrous oxide method for quantitative determination of cerebral blood flow in man. This procedure is based on determination of the rate at which nitrous oxide breathed in a gaseous mixture at low concentration equilibrates with brain tissue. This equilibration occurs within ten minutes, and from a mathematical analysis of the curves of nitrous oxide concentration in arterial and venous blood during this period, and the use of Fick's principle, the cerebral blood flow can be obtained. Kety and Schmidt have checked their method by direct measurement in the monkey with a bubble flow meter, and by a comparison of the brain concentration of nitrous oxide with blood concentration at equilibrium. In 14 healthy young men, cerebral blood flow was 54 cc per minute per 100 gm of brain tissue, with a deviation of plus or minus 12 cc per minute. A mean value of cerebral oxygen consumption was found to be 3.3 cc per 100 gm of brain tissue per minute, with a deviation of plus or minus 0.4 cc. By the use of this procedure, Kety and Schmidt²⁵ studied the effect of altered arterial tensions of carbon dioxide and oxygen on cerebral blood flow. Increased arterial carbon dioxide tension produced an increase in cerebral blood flow averaging 75 per cent. High oxygen tensions were associated with a reduction in cerebral blood flow of 13 per cent, whereas anoxemia was associated with an increase of 35 per cent in flow. Measurement of cerebral oxygen consumption showed that no changes occurred in this metabolic activity as a result of changes in arterial tensions of oxygen and carbon dioxide producing the changes in blood flow described.

In a further study, Kety, Shenkin and Schmidt²⁶ studied the relations between cerebral circulation and

intracranial pressure In 12 patients with brain tumors, the rise in cerebrospinal-fluid pressure produced by the brain tumor was associated with a progressive increase in mean arterial blood pressure and cerebrovascular resistance and, above a critical level of cerebrospinal-fluid pressure equivalent to about 450 mm of water, with a definite decrease in cerebral blood flow In this group of patients with increased intracranial pressure, a good correlation between state of consciousness and cerebral oxygen consumption was found The conscious patients yielded a mean value for cerebral oxygen consumption of 3.1 cc per 100 gm of brain tissue per minute, whereas the comatose group averaged 2.5 cc per 100 gm per minute, the average in normals being 3.3 cc per 100 gm per minute Similarly, the patients with cerebral blood flow below 40 cc per 100 gm per minute were all comatose

An interesting study of the physiology of the circle of Willis has been carried out by Rogers.²⁷ Since the time of Willis, who introduced the concept, many have considered that his structure acts as a reservoir, or distributor station, serving equally all vessels leading from it and, consequently, equalizing cerebral blood flow Alternatively, the circle may be conceived as acting merely as an anastomosis, with the potentiality of opening up should a major vessel supplying it be occluded Rogers reports on the anatomy of the structure, injection studies in cadavers, cerebral arteriography in the living and the behavior of a working scale model Anatomically, he has found that the circle of Willis is almost always a closed ring, but that considerable variation occurs in the size of component vessels Injections of methylene blue kept the dye for the most part in the postcircle distribution of the artery, which was injected proximal to the circle In patients on whom cerebral arteriography was done, injections into the carotid arteries on one side was followed by distribution of the injection mass mostly into the middle and anterior cerebral arteries on the side of the injection The working model of the circle of Willis constructed by Rogers gave results in injection experiments similar to those described on cadavers Rogers states that the result of carotid ligation is a reduction of flow in aneurysms of vessels distal to the circle on the side of the ligation, concluding that these findings support the idea that the circle of Willis works as an anastomosis, and not as a reservoir

Although cerebral hemorrhage commonly takes the form of massive intracapsular bleeding in an arteriosclerotic subject in the older age group, less frequently hemorrhage occurs elsewhere in the brain in a young and apparently healthy person Jewesbury²⁸ has discussed the etiology, clinical picture and treatment of the latter group He points out that small intracerebral aneurysms, angiomas and other vascular anomalies have rather fre-

quently been identified as the source of the hemorrhage Less frequently, eclampsia, polyarteritis nodosa, mycotic aneurysm and cerebral tumor are the basis of hemorrhage He states that head injury, even when apparently slight, is an important etiologic factor, and may produce immediate or delayed effects There are a number of cases in which no adequate explanation of the bleeding can be given In the majority of these patients the clinical picture is that of a slowly expanding intracerebral lesion, and not one of sudden apoplexy This kind of clinical picture results from the development of a subcortical hematoma, which tends to become encysted and to increase slowly in size Jewesbury reports a number of cases of this type that have responded well to evacuation of the cyst by surgical intervention

Krainer²⁹ has reported 7 fatal cases of cerebral thrombosis in young Indian adults, 3 of which were due to thrombosis of infected cerebral arteries Two of the patients had syphilis, 1 had cerebral malaria, and 1 had thrombosis in association with a spontaneous aneurysm Three cases were caused by thrombosis of infected cerebral arteries, which were thought to be due to transpulmonary embolism of infective particles, from foci in the systemic circulation

One hundred and thirty patients with subarachnoid hemorrhage have been analyzed by Hamby.³⁰ Forty-four of 47 proved cases were caused by ruptured aneurysms In 23 of 44 fatal cases, intracerebral hematomas were present Of the 130 patients, 67 died in the hospital A follow-up report on 62 of the 63 patients who left the hospital shows that 17 have died Of the 45 living patients, 21 have recovered completely, 13 are able to work despite neurologic handicaps, and 11 are invalids Hamby reports that unfavorable prognostic features are previous attacks, recurrent episodes of bleeding while the patient is in the hospital, and the presence of mental disturbances, unconsciousness and convulsions

Wechsler and Gross³¹ have described the usefulness of cerebral arteriography as both a diagnostic and a therapeutic guide in patients with spontaneous and subarachnoid hemorrhages Subarachnoid hemorrhage was associated with a vascular anomaly in 6 of 10 cases reported, and with an aneurysm in 4

Gilbert and de Takats³² reported on the results of blocking of the cervical sympathetic trunk with procaine on the side of the lesions in 25 patients with apoplexy A transient improvement was noted in 19 patients, manifested by a return of consciousness and of speech, and enhanced motor performance The authors suggest that this procedure, along with other means of combating cerebral edema and stasis, is of value in the treatment of apoplexy

Sindell³² has stated that 3 patients, in hypoglycemic coma during insulin shock therapy, were brought out of coma by the administration of either amyl nitrite or nicotinic acid, or both. He suggests that the use of vasodilators is valuable in the treatment of patients with apparently irreversible hypoglycemic coma.

The cold-pressor reaction has been studied in psychotic patients with cerebrovascular disease by Becker and his co-workers³⁴. They report evidence that there is an increased response to the vasopressor test in such patients. Persons with well advanced cerebral arteriosclerosis showed the most marked response.

Zeman and Siegal³⁵ have described the development of a permanent paralysis of the right arm in an eighty-three-year-old man with long-standing hypertension following massage, alternately, of the carotid sinuses. They state that 8 cases of irreversible cerebral changes, occurring after carotid-sinus pressure, have been reported in the literature. These accidents have taken place, usually, in elderly patients.

A study of hypertensive encephalopathy has been made by Pickering³⁶. He divided this condition into two distinct forms. In the first form, acute hypertension, or chronic hypertension with an acute exacerbation of hypertension, may be associated with headaches, vomiting, convulsions and coma, as the result of acute edema of the brain. Pickering explains these symptoms on the basis of "defective constriction" of cerebral vessels with the increased intravascular pressure, which is present in association with the hypertension, leading to an outflow of fluid into the brain. In the second form, which is associated with chronic hypertension, Pickering thinks attacks of local motor or sensory paralysis are the result of sudden arterial occlusion of larger or smaller vessels, caused, perhaps, by a thrombus. He attributes the phenomena of hypertensive encephalopathy to mechanisms other than arterial spasm for several reasons. He points out that cerebral vessels have poor musculature, and that they constrict feebly in response to known vasoconstrictor agents. Also in many of his patients with chronic hypertension, Pickering was unable to draw a sharp dividing line between bouts of paralysis lasting for a short while, and those lasting permanently, which he regards as an argument against vasospasm as the cause of the symptomatology.

MYASTHENIA GRAVIS AND FAMILIAL PERIODIC PARALYSIS

Approximately 200 patients with myasthenia gravis have undergone thymectomy as treatment for their disease. Harvey³⁷ has pointed out that 15 per cent of these patients show marked improvement, and has commented that an analysis of why the operation failed to result in marked improve-

ment in the other 85 per cent should be of value in understanding the disease. In discussing the results of thymectomies done at Johns Hopkins Hospital, he states that the two factors most favorable for good response to the procedure are performance of the operation early in the course of the disease and prior administration of only small amounts of neostigmine. Harvey states that it is not necessary for a thymoma to be present for a remission to occur after thymectomy, since some patients whose thymus glands show only moderate hyperplasia also improve. Incidentally, a thymoma, if present, may not be demonstrable by x-ray examination. Histologically, the tumors removed at Johns Hopkins Hospital have shown varying amounts of neoplastic tissue, which arises from epithelial cells of the thymus reticulum, lymphocytic hyperplasia is also present. Patients who have shown a response to thymectomy manifested improvement of strength predominantly in their limb and trunk muscles, with less increase of power in muscles supplied by cranial nerves.

Tetra-ethylpyrophosphate (TEPP), a drug with a powerful anticholinesterase activity, has been introduced recently by Burgen and his colleagues³⁸ for the treatment of myasthenia gravis, and promises to be of considerable value. This drug, whose actions are reported to resemble those of eserine and neostigmine more closely than those of diisopropyl fluorophosphate (DFP), is as potent as eserine and a third as potent as neostigmine in tests on rats. The duration of its action, however, is twenty-four to forty-eight hours, in contrast with the two to three hours that is the period of action of eserine and neostigmine. TEPP is well absorbed when given by mouth.

When given orally to 3 patients with myasthenia, TEPP was found to be a completely effective substitute for neostigmine, and, because of its longer action, its effect was much smoother than that of neostigmine. Burgen et al³⁸ state that they have found 10 mg of TEPP given by mouth to be as effective as oral doses of 100 to 150 mg of neostigmine. The maintenance dose of TEPP varies from 8 to 12 mg daily, administered orally in two or three doses.

The side actions of TEPP consist in visceral and central effects similar to those of neostigmine. The most pronounced side action is on the gastrointestinal tract, colic and diarrhea being produced. This visceral action is prevented effectively by atropine. The central side effects, produced in all of Burgen's patients during dose stabilization, included vertigo and nystagmus. Nausea and vomiting, sweating and pallor also occur. The last two groups of effects were not prevented by atropine.

Grob and his associates³⁹⁻⁴¹ have summarized their extensive clinical research with diisopropyl fluorophosphate (DFP). They find that whereas administration of DFP to patients with myasthenia

intracranial pressure In 12 patients with brain tumors, the rise in cerebrospinal-fluid pressure produced by the brain tumor was associated with a progressive increase in mean arterial blood pressure and cerebrovascular resistance and, above a critical level of cerebrospinal-fluid pressure equivalent to about 450 mm of water, with a definite decrease in cerebral blood flow In this group of patients with increased intracranial pressure, a good correlation between state of consciousness and cerebral oxygen consumption was found The conscious patients yielded a mean value for cerebral oxygen consumption of 3.1 cc per 100 gm of brain tissue per minute, whereas the comatose group averaged 2.5 cc per 100 gm per minute, the average in normals being 3.3 cc per 100 gm per minute Similarly, the patients with cerebral blood flow below 40 cc per 100 gm per minute were all comatose

An interesting study of the physiology of the circle of Willis has been carried out by Rogers.²⁷ Since the time of Willis, who introduced the concept, many have considered that his structure acts as a reservoir, or distributor station, serving equally all vessels leading from it and, consequently, equalizing cerebral blood flow Alternatively, the circle may be conceived as acting merely as an anastomosis, with the potentiality of opening up should a major vessel supplying it be occluded Rogers reports on the anatomy of the structure, injection studies in cadavers, cerebral arteriography in the living and the behavior of a working scale model Anatomically, he has found that the circle of Willis is almost always a closed ring, but that considerable variation occurs in the size of component vessels Injections of methylene blue kept the dye for the most part in the postcircle distribution of the artery, which was injected proximal to the circle In patients on whom cerebral arteriography was done, injections into the carotid arteries on one side was followed by distribution of the injection mass mostly into the middle and anterior cerebral arteries on the side of the injection The working model of the circle of Willis constructed by Rogers gave results in injection experiments similar to those described on cadavers Rogers states that the result of carotid ligation is a reduction of flow in aneurysms of vessels distal to the circle on the side of the ligation, concluding that these findings support the idea that the circle of Willis works as an anastomosis, and not as a reservoir

Although cerebral hemorrhage commonly takes the form of massive intracapsular bleeding in an arteriosclerotic subject in the older age group, less frequently hemorrhage occurs elsewhere in the brain in a young and apparently healthy person Jewesbury²⁸ has discussed the etiology, clinical picture and treatment of the latter group He points out that small intracerebral aneurysms, angiomas and other vascular anomalies have rather fre-

quently been identified as the source of the hemorrhage Less frequently, eclampsia, polyarteritis nodosa, mycotic aneurysm and cerebral tumor are the basis of hemorrhage He states that head injury, even when apparently slight, is an important etiologic factor, and may produce immediate or delayed effects There are a number of cases in which no adequate explanation of the bleeding can be given In the majority of these patients the clinical picture is that of a slowly expanding intracerebral lesion, and not one of sudden apoplexy This kind of clinical picture results from the development of a subcortical hematoma, which tends to become encysted and to increase slowly in size Jewesbury reports a number of cases of this type that have responded well to evacuation of the cyst by surgical intervention

Krainer²⁹ has reported 7 fatal cases of cerebral thrombosis in young Indian adults, 3 of which were due to thrombosis of infected cerebral arteries Two of the patients had syphilis, 1 had cerebral malaria, and 1 had thrombosis in association with a spontaneous aneurysm Three cases were caused by thrombosis of infected cerebral arteries, which were thought to be due to transpulmonary embolism of infective particles, from foci in the systemic circulation

One hundred and thirty patients with subarachnoid hemorrhage have been analyzed by Hamby.³⁰ Forty-four of 47 proved cases were caused by ruptured aneurysms In 23 of 44 fatal cases, intracerebral hematomas were present Of the 130 patients, 67 died in the hospital A follow-up report on 62 of the 63 patients who left the hospital shows that 17 have died Of the 45 living patients, 21 have recovered completely, 13 are able to work despite neurologic handicaps, and 11 are invalids Hamby reports that unfavorable prognostic features are previous attacks, recurrent episodes of bleeding while the patient is in the hospital, and the presence of mental disturbances, unconsciousness and convulsions

Wechsler and Gross³¹ have described the usefulness of cerebral arteriography as both a diagnostic and a therapeutic guide in patients with spontaneous and subarachnoid hemorrhages Subarachnoid hemorrhage was associated with a vascular anomaly in 6 of 10 cases reported, and with an aneurysm in 4

Gilbert and de Takats³² reported on the results of blocking of the cervical sympathetic trunk with procaine on the side of the lesions in 25 patients with apoplexy A transient improvement was noted in 19 patients, manifested by a return of consciousness and of speech, and enhanced motor performance The authors suggest that this procedure, along with other means of combating cerebral edema and stasis, is of value in the treatment of apoplexy

phate effects an irreversible inhibition of cholinesterase, the enzyme that hydrolyzes acetylcholine, and thus produces an accumulation of acetylcholine. These workers have correlated their findings with the recent evidence indicating that certain kinds of convulsions are related to abnormalities of acetylcholine metabolism. It is interesting to compare this study with that of Pope et al,⁵⁰ who have shown that in trigger areas of the cortex of animals with experimentally induced focal epilepsy, there is an increase in cholinesterase concentration.

The results of a decade of systematic investigation into the anticonvulsant action of many classes of compounds have been summarized by Merritt and Brenner.⁵¹ Over 700 compounds were first investigated for their action in protection of cats against electrically induced convulsions. About 10 per cent of the 700 compounds were found to produce a significant elevation of the convulsive threshold in acute experiments.

Classes of compounds found to possess activity in raising electrical threshold include barbiturates, benzoazoles, hydantoinates, ketones, oxazolidinediones and phenyl compounds containing sulfur. So far only a few of these compounds have been tested clinically. Of those tested, 5,5 diphenylhydantoin (dilantin) has proved to be the most effective anticonvulsant yet discovered. Of possible equal or greater value is 5 methyl, 5 phenyl hydantoin. The latter compound is not suitable for general use because of its toxicity.

Ellermann⁵² has reported on the use of 5,5-diphenyl-2,4-dioxazolidinedione (epidon) in epilepsy. Apparently, on the basis of records of patients presented, the drug when administered in dosages of 2 or 3 gm daily is effective in controlling grand-mal and psychomotor seizures. It is not possible from the cases quoted in Ellermann's article to compare the effectiveness of epidon with that of other anticonvulsants such as dilantin, since the patients described were not receiving adequate dilantin therapy at the time they were started on epidon. Ellermann states that toxic reactions with epidon were a fifth as frequent as those with dilantin.

As an assay of the efficacy of anticonvulsants, the activity of various drugs in preventing the tonic phase of electroshock in nonepileptic subjects has been introduced by Toman et al.⁵³

Another fatal case of acute pancytopenia following tridione therapy has been reported.⁵⁴ This brings the total of reported deaths to 3. In a careful and convincing study, Barnett, Simons and Wells⁵⁵ have described a patient who on three occasions developed a nephrotic syndrome following administration of tridione. These reports emphasize the necessity of repeated blood and urine examination in patients receiving this substance.

Russell⁵⁶ has employed a technic of correlating the areas of cortex involved in head wounds with the incidence of post-traumatic epilepsy in patients who have received head wounds. Although casual inspection of the cortical maps presented impresses one with a predominance of involvement in the "suppressor" areas of cortex in patients who develop traumatic epilepsy, R. A. Fisher has analyzed the maps and has concluded that there is no statistically significant difference in location of wounds in the two groups of patients.

Recent work by Elvehjem and his colleagues⁵⁷ at Wisconsin, on the production of running fits in dogs by white flour bleached by the "agene" process with nitrogen trichloride, has aroused interest in the possible role of flour so manufactured in epilepsy in human beings. However, that there is a species difference in the effect of the "agenized flour" is illustrated by the fact that although feeding of this substance to cats and dogs produced fits, monkeys so treated did not develop them but did show some changes in their electroencephalograms, and that 12 human beings fed highly agenized products for two to four weeks did not show either convulsions or electroencephalographic changes.⁵⁷ The fraction of flour showing the toxic factor has been demonstrated to be the wheat protein, and not the lipid or carbohydrate fraction. Of course, epilepsy in its form known today in human patients plagued man long before "agenized" flour was ever manufactured.

Abbott and Schwab,⁵⁸ in analyzing patients with epilepsy showing normal electroencephalograms between seizures, point out that such patients have a better prognosis with respect to frequency of future spell, response to medicine, likelihood of remissions while off medication and capacity for work, than those with abnormal records between convulsions. Their patients with abnormal inter-seizure patterns usually had had convulsions in childhood, or had suffered brain injuries.

INFECTIONS

Reports on the efficacy of penicillin in the treatment of neurosyphilis continue to appear.⁵⁹⁻⁶¹ Thus, Dattner and his co-workers⁵⁹ report satisfactory results in 151 patients with both asymptomatic and symptomatic neurosyphilis. They employ 40,000 units of penicillin given intramuscularly every three hours for 150 doses, a total of 6,000,000 units, 90 per cent of their patients gave satisfactory responses and these investigators believe that penicillin is as effective as and will eventually replace fever therapy.

Heiman,⁶⁰ however, recommends penicillin for asymptomatic and early symptomatic syphilis, but believes that fever therapy should be used in treating late symptomatic neurosyphilis.

Isolated cases of the apparent cure of tuberculous meningitis have been reported. Mehas and Truax⁶¹

gravis results in considerable gain in strength, in no case was the improvement as great as that obtained with neostigmine, and they believe that the unpleasant central nervous and gastrointestinal symptoms produced by DFP preclude its use in amounts sufficient to produce therapeutic effects. They have found evidence that DFP and neostigmine compete for cholinesterase (Ch-E) and that formation of a neostigmine-Ch-E complex prevents irreversible inhibition of Ch-E by subsequently injected DFP, thereby blocking the effect of DFP.

Torda and Wolff⁴² have reported that injections of a mixture of essential amino acids effect an increase in strength of patients with myasthenia, presumably through influencing acetylcholine synthesis.

In familial periodic paralysis, the close association of a fall in concentration of serum potassium with the onset of muscular paralysis and the relief of muscle weakness that ensues after administration of potassium salts are both well known and indicate that a defect in potassium metabolism is involved in the pathological physiology of this disease. The nature of the disorder of potassium metabolism is not understood, however.

Danowski et al.⁴³ have studied, in a quantitative manner, the exchange of potassium and sodium between the extracellular and intracellular phases of the body fluids in 2 patients with this disease. They found that during the development of paralysis, potassium shifted from the extracellular to the intracellular phase, with a resultant sharp decline in serum potassium concentrations. During recovery, large amounts of administered potassium were taken up by the intracellular phase before extracellular loss was replenished. Reciprocal transfer of sodium was observed in one patient, but not in the other. No significant changes occurred in the volume of total body water and extracellular fluid, and there was no increase in potassium excretion in urine or feces.

Gass et al.,⁴⁴ in a study of a patient with familial periodic paralysis by means of radioactive potassium, were unable to detect, with a surface Geiger counter, any increase in radioactivity over either muscles or liver in an induced attack of paralysis. Nor could they find a shift of potassium into spinal fluid or red cells. Thus, although from the study of Danowski and his co-workers⁴³ it appears clear that during an attack of paralysis potassium moves into the intracellular phase of the body fluid of the patient, and is not excreted in the urine or feces, on the basis of Gass's work it is not possible to determine into which particular organ or cellular system the potassium migrates. It should be pointed out that there are certain equivocal aspects to the observations of the latter investigators, and further studies with tracer or other appropriate techniques may well show that the potassium moves into the muscle at the onset of paralysis.

MULTIPLE SCLEROSIS

Although previous reports have described the production of such lesions in monkeys by similar methods, the production of disseminated encephalomyelitis in rabbits by the injection of homologous spinal-cord homogenates with adjuvants has now been reported by Morrison.⁴⁵

Langworthy⁴⁶ has discussed a number of patients suffering from multiple sclerosis who showed signs of conversion hysteria either before or after the development of signs of organic disease. These patients also manifested pronounced evidences of vasomotor instability in their extremities, and Langworthy asks whether vascular changes in the brain related to neurotic difficulties may not lead in turn to organic disease. Langworthy believes that psychotherapy offers as hopeful an approach to the therapy of multiple sclerosis as any other treatment now available.

Eighteen patients with multiple sclerosis who showed constrictions of retinal arterioles have been reported by Franklin and Brickner.⁴⁷ In one of their patients, constriction was seen in a retinal venule. Frequently, scotomas and, occasionally, a reduction in visual acuity, associated with the arteriolar constriction, were also present. The objective findings are stated to have coincided with the subjective complaints of the patients. In most cases in which they were employed, fast acting, vasodilating drugs such as amyl nitrite, administered by inhalation, caused prompt, temporary relaxation of the arteriolar constrictions and, concomitantly, a reduction in the size of the scotoma. In several cases, an increase of visual acuity was noted in patients in whom a reduction of acuity was associated with arteriolar constriction. Franklin and Brickner regard the constrictions as spasms of arterioles, and they develop the hypothesis that the lesions throughout the central nervous system in multiple sclerosis are caused by diminution of the blood supply to neural tissue resulting from vasospasm.

In an investigation of the loss of axis cylinders in sclerotic plaques by means of the Bodian silver stain, Putnam and Alexander⁴⁸ state that some degree of damage or destruction of axons occurred in all the sclerotic plaques investigated. Similar changes of a corresponding degree of intensity were seen in other central-nervous-system lesions of vascular origin.

EPILEPSY

Himwich and his colleagues⁴⁹ have described the appearance of high-amplitude waves of grand-mal type in the electroencephalogram of rabbits after the injection of di-isopropyl fluorophosphate into a carotid artery. The high-amplitude waves appear first in the cortex on the injected side, subsequently spread to the opposite cortex and are maintained for an hour. Di-isopropyl fluorophos-

The clinical characteristics of an epidemic of Japanese B encephalitis occurring as an outbreak in the civilian population of Okinawa have been reported by Lewis et al.⁷⁵ Among 63 patients, most of whom were children, the mortality was approximately 20 per cent. The clinical manifestations were characteristic of a diffuse encephalomyelitis and resembled those of other neurotropic virus infections. Permanent disorders of the nervous system of variable degree resulted in a fifth of the patients. A postencephalitic parkinsonian syndrome occurred rarely. It was found that accurate diagnosis depended upon the use of specific serologic and virologic tests.

Gibbs and Gibbs⁷⁶ have analyzed the electroencephalographic findings in 240 cases of encephalitis in various stages of the disease. They state that the abnormalities are often focal and can be correlated with the stage of the disease. During the acute and subacute phases the electroencephalographic findings correlate with the general severity of symptoms. However, the only feature of the postencephalitic syndrome that correlates highly with electroencephalographic abnormality is the presence of convulsions. The electroencephalogram has diagnostic value for encephalitis, and after the acute phase is past it has prognostic value for postencephalitic epilepsy. Wave and spike activity of the petit-mal type is a common sequel of encephalitis in children.

Hoyne and Schultz⁷⁷ have reported the case of a patient who had five attacks of meningitis in five years, four of them resulting from a pneumococcus, and the fifth from *H influenzae*. At autopsy, two small, inexplicable perforations were found behind the crista galli that led into the ethmoid cells and nasopharynx. The authors suggest that every patient with pneumococcal meningitis have skull x-ray films taken with special reference to the sinuses.

MISCELLANEOUS CONSIDERATIONS

Neuropathological aspects of thrombocytic angiothrombosis have been detailed by Adams, Cammermeyer and Fitzgerald.⁷⁸ This name is applied to a rare disease, of which 13 cases are described in the literature. The etiology is unknown. The disease is characterized by fever, malaise and cerebral symptoms ranging from muscular weakness, hemiplegia, convulsions and confusion to coma. Hematologically, an anemia and thrombopenia are present. The disease runs a rapidly progressive course, death ensuing in from a few days to eight weeks. Neuropathologically, platelet thrombi are found in cerebral vessels, sometimes associated with multiple small foci of parenchymal necrosis and petechial hemorrhages. A clinicoanatomic correlation of neurologic symptoms is usually not possible. This condition must be distinguished clinically from idiopathic thrombopenic purpura,

lupus erythematosus subacute bacterial endocarditis and rickettsial infections. The differentiation may be possible on the basis of the total clinical picture and laboratory data. The diagnosis could probably also be established by bone-marrow autopsy, since platelet thrombi and vascular hyperplasia are often observable in the bone marrow.

Bethell and Sturgis⁷⁹ have described 70 cases of pernicious anemia studied over periods of not less than ten years. Most of the patients, whether treated with oral preparations of stomach or liver, or parenteral crude or refined liver extracts, showed significant improvement in their neurologic manifestations. The period of improvement was limited essentially to the first year of therapy. Thirty-six patients who had regular therapy and complete hematologic remission afforded no case of development or progression of neurologic symptoms, 15 patients who did not adhere to optimal therapy, and who had abnormal blood values, showed transient and reversible neurologic manifestations, which cleared up on resumption of therapy, and 19 patients who suffered clinical and hematologic relapses manifested only rarely serious progression of neurologic disease. However, the authors point out that these results do not justify the conclusion that irregular or suboptimal therapy of pernicious anemia is without serious possibilities.

Ross and his collaborators,⁸⁰ reporting on the use of folic acid in the treatment of pernicious anemia, state that 11 of their patients developed, or showed progression of, subacute combined degeneration of the spinal cord during folic acid therapy. Neurologic involvement developed in most of these patients when the peripheral blood was normal. The institution of liver-extract therapy, in addition to folic acid maintenance therapy, failed to prevent progression of the disease in 4 patients, and only partially arrested the disease in the fifth, in whom, indeed, improvement occurred more rapidly when folic acid was discontinued. In the experience of these physicians, subacute combined degeneration of the spinal cord occurred with greater frequency in patients on large daily doses of folic acid than it did in patients with small or intermittent doses. They suggest that folic acid in large daily doses may actually precipitate or aggravate neurologic disease.

Friedman and Brenner⁸¹ report that the intravenous injection of 100 mg of sodium nicotinate did not produce relief of pain in any of 7 patients suffering from acute migraine attacks. These investigators did not find this compound to be any more effective in the symptomatic relief of patients with psychogenic or post-traumatic headache than physiologic solution of sodium chloride injected intravenously in small amounts.

Mills⁸² has reported that potassium thiocyanate is of some value in the relief of headaches suffered by patients with benign and malignant hyperten-

have described a thirty-one-year-old woman with proved tuberculous meningitis in whom intramuscular and intrathecal streptomycin apparently arrested the progress of the disease. Appelbaum and Halkin⁶⁶ report the case of a nine-year-old boy with tuberculous meningitis and pulmonary miliary tuberculosis whose disease was completely arrested by intrathecal and intramuscular administration of streptomycin. Although in the former patient residual damage to the central nervous system was present, in the latter there were no neurologic residua.

Now that there is a hopeful therapeutic procedure for this previously incurable malady, the necessity of early diagnosis of tuberculous meningitis increases. This is especially true since the chance of avoiding serious, permanent, neurologic sequelae probably depends on early institution of therapy.⁶⁷ Tuberculous meningitis is commonest in the first decade of life, and therefore it is in young children that particular watch must be kept for early signs. It has been emphasized⁶⁷ that the presenting features of tuberculosis of the meninges are many and varied, but that most cases conform to a general pattern of symptomatology. Most often the meningitis begins insidiously, with symptoms mimicking minor ailments. Rarely, the onset of tuberculous meningitis is sudden, with focal signs in the nervous system, such as cranial-nerve palsies, limb paralyzes and focal and generalized convulsions. Headache, fever and stiff neck are frequently present. Demonstration of a low and falling spinal-fluid sugar value is of great diagnostic help in early stages.

Paine et al⁶⁸ have described the use of streptomycin in the treatment of certain gram-negative bacillus infections of the central nervous system. Two patients with *Pseudomonas aeruginosa* infection, 2 with Type B *Haemophilus influenzae* infections, and 1 patient with *Proteus vulgaris* infection all recovered after treatment with streptomycin. Streptomycin was given intrathecally in doses of 0.05 gm in 1 cc of sterile physiologic saline solutions daily. Concomitantly, streptomycin was administered intramuscularly in doses varying from 0.02 gm to 4 gm every six hours. The fact that fever may rise during streptomycin therapy, as a result of drug toxicity, makes it difficult to decide at what point treatment should be terminated. Frequent cultures of the spinal fluid are a helpful guide in making this decision.

Hoynes and Brown⁶⁹ have reported a series of 30 patients with type B *H. influenzae* meningitis, 28 of whom recovered after treatment with various combinations of specific serum, sulfonamides and streptomycin. They emphasize particularly that 23 of the 28 patients who recovered received no intrathecal therapy.

Accounts of the involvement of the nervous system in trichiniasis have recently appeared

MacAndrew and Davis⁷⁰ have reported the case of a thirty-nine-year-old woman with trichiniasis whose presenting symptoms were right footdrop and right-facial-muscle palsy. These writers point out the importance of consideration of this disease in diagnosis of patients with unexplained neuritis. Skinner⁷¹ has described 2 cases of depression and delirium in which trichiniasis was present. The clinical condition of 1 of the patients resembled delirium tremens.

Collard and Kendall⁷² have presented the case of a patient with cerebral amebiasis whom they successfully treated with emetine. The authors state that this patient is the first reported in the literature who has recovered from amebiasis of the central nervous system. This condition has had a fatal outcome even after therapy with emetine or evacuation of amebic cerebral abscesses neurosurgically in all patients heretofore reported. Collard and Kendall attribute the recovery of their patient to early institution of treatment, probably at a stage of focal amebic encephalitis, before actual abscess formation had occurred.

A comprehensive report on involvement of the nervous system in schistosomiasis has been made by Kane and Most,⁷³ who point out that the three species of schistosome demonstrate predilections for localizing in different parts of the central nervous system. Thus, *S. japonica* invades the brain, whereas *S. mansoni* and *S. haematobium* go invariably to the spinal cord. Correspondingly, the symptomatology varies, *S. japonica* manifesting itself by diffuse encephalitic symptoms, focal paralyzes, epileptic seizures or signs of an expanding intracranial lesion. On the other hand, *S. mansoni* and *S. haematobium* produce signs of myelitis or spinal-cord compression. The authors emphasize the fact that the diagnosis of this condition should be considered in any patient with these findings who has been exposed to possibly infected fresh water in any one of the endemic areas in the South Pacific Area (Japan, Formosa, China and the Philippines). It may be as long as four years after infection before central-nervous-system involvement is manifested. The treatment described by Kane and Most consisted usually in administration of antimony potassium tartrate, accompanied, if the clinical condition made it necessary, by appropriate surgical intervention. Prognosis is usually good for arrest of the disease but, of course, neural tissue destroyed before treatment is instituted will not be restored.

A patient with a large granulomatous tumor in the right occipitoparietal region of the brain, caused by infestation with *S. japonica*, has been described by Reeves and Kerr.⁷⁴ The preoperative diagnosis was an expanding intracranial lesion, and the possibility of its being on the basis of schistosomiasis was not seriously considered, since no historical or clinical evidence pointed to the parasite, except for exposure in the endemic areas of Leyte and Mindoro.

The clinical characteristics of an epidemic of Japanese B encephalitis occurring as an outbreak in the civilian population of Okinawa have been reported by Lewis et al.⁷⁵ Among 63 patients, most of whom were children, the mortality was approximately 20 per cent. The clinical manifestations were characteristic of a diffuse encephalomyelitis and resembled those of other neurotropic virus infections. Permanent disorders of the nervous system of variable degree resulted in a fifth of the patients. A postencephalitic parkinsonian syndrome occurred rarely. It was found that accurate diagnosis depended upon the use of specific serologic and virologic tests.

Gibbs and Gibbs⁷⁶ have analyzed the electroencephalographic findings in 240 cases of encephalitis in various stages of the disease. They state that the abnormalities are often focal and can be correlated with the stage of the disease. During the acute and subacute phases the electroencephalographic findings correlate with the general severity of symptoms. However, the only feature of the postencephalitic syndrome that correlates highly with electroencephalographic abnormality is the presence of convulsions. The electroencephalogram has diagnostic value for encephalitis, and after the acute phase is past it has prognostic value for postencephalitic epilepsy. Wave and spike activity of the petit-mal type is a common sequel of encephalitis in children.

Hoynes and Schultz⁷⁷ have reported the case of a patient who had five attacks of meningitis in five years, four of them resulting from a pneumococcus, and the fifth from *H. influenzae*. At autopsy, two small, inexplicable perforations were found behind the crista galli that led into the ethmoid cells and nasopharynx. The authors suggest that every patient with pneumococcal meningitis have skull x-ray films taken with special reference to the sinuses.

MISCELLANEOUS CONSIDERATIONS

Neuropathological aspects of thrombocytic angiothrombosis have been detailed by Adams, Cammermeyer and Fitzgerald.⁷⁸ This name is applied to a rare disease, of which 13 cases are described in the literature. The etiology is unknown. The disease is characterized by fever, malaise and cerebral symptoms ranging from muscular weakness, hemiplegia, convulsions and confusion to coma. Hematologically, an anemia and thrombopenia are present. The disease runs a rapidly progressive course, death ensuing in from a few days to eight weeks. Neuropathologically, platelet thrombi are found in cerebral vessels, sometimes associated with multiple small foci of parenchymal necrosis and petechial hemorrhages. A clinicoanatomic correlation of neurologic symptoms is usually not possible. This condition must be distinguished clinically from idiopathic thrombopenic purpura,

lupus erythematosus subacute bacterial endocarditis and rickettsial infections. The differentiation may be possible on the basis of the total clinical picture and laboratory data. The diagnosis could probably also be established by bone-marrow autopsy, since platelet thrombi and vascular hyperplasia are often observable in the bone marrow.

Bethell and Sturgis⁷⁹ have described 70 cases of pernicious anemia studied over periods of not less than ten years. Most of the patients, whether treated with oral preparations of stomach or liver, or parenteral crude or refined liver extracts, showed significant improvement in their neurologic manifestations. The period of improvement was limited essentially to the first year of therapy. Thirty-six patients who had regular therapy and complete hematologic remission afforded no case of development or progression of neurologic symptoms, 15 patients who did not adhere to optimal therapy, and who had abnormal blood values, showed transient and reversible neurologic manifestations, which cleared up on resumption of therapy, and 19 patients who suffered clinical and hematologic relapses manifested only rarely serious progression of neurologic disease. However, the authors point out that these results do not justify the conclusion that irregular or suboptimal therapy of pernicious anemia is without serious possibilities.

Ross and his collaborators,⁸⁰ reporting on the use of folic acid in the treatment of pernicious anemia, state that 11 of their patients developed, or showed progression of, subacute combined degeneration of the spinal cord during folic acid therapy. Neurologic involvement developed in most of these patients when the peripheral blood was normal. The institution of liver-extract therapy, in addition to folic acid maintenance therapy, failed to prevent progression of the disease in 4 patients, and only partially arrested the disease in the fifth, in whom, indeed, improvement occurred more rapidly when folic acid was discontinued. In the experience of these physicians, subacute combined degeneration of the spinal cord occurred with greater frequency in patients on large daily doses of folic acid than it did in patients with small or intermittent doses. They suggest that folic acid in large daily doses may actually precipitate or aggravate neurologic disease.

Friedman and Brenner⁸¹ report that the intravenous injection of 100 mg of sodium nicotinate did not produce relief of pain in any of 7 patients suffering from acute migraine attacks. These investigators did not find this compound to be any more effective in the symptomatic relief of patients with psychogenic or post-traumatic headache than physiologic solution of sodium chloride injected intravenously in small amounts.

Mills⁸² has reported that potassium thiocyanate is of some value in the relief of headaches suffered by patients with benign and malignant hyperten-

sion Symptomatic relief resulted in patients in whom no fall of blood pressure was noted Administration of thiocyanate afforded no relief of headache in patients with malignant hypertension whose blood urea nitrogen was elevated

Dow and Whitty⁸³ have made an electroencephalographic study of 51 patients with migraine headaches Generalized dysrhythmia was observed in 14, symmetrical, bilateral, episodic, abnormal activity in 12, and a persistent abnormality in 4 Exaggeration of a previous abnormality was noted at the period of aura in 5 of 8 cases, and after ergotamine tartrate administration in 3 of 5 cases The transient focal abnormality described by Engel et al⁸⁴ was not observed

A simple classification of headaches has been suggested by Butler and Thomas⁸⁵ on the basis of mechanism of their production These authors suggest dividing headaches into vascular headaches, including migraine, histamine, cephalalgia and tension headache, psychic headache, intracranial traction headache, extracranial headache due to irritation of afferent cranial or cervical nerves, combined intracranial and extracranial headache, and toxic or mixed headache

Robertson et al⁸⁶ have investigated the nature of pains in the head and face arising from diseased or experimentally stimulated teeth Head pain associated with prolonged toothache and located at a distance from the painful tooth itself was found to be of two types The first is that associated with sustained contraction of muscles of the head and neck, and the second that which is on the basis of referred pain in the distribution of the trigeminal nerve

Ingraham and Cobb⁸⁷ have reported on their clinical experience with diodrast in cerebral arteriography, and state that this substance is safer than thorotrast and is as satisfactory in this procedure

Falconer, McGeorge and Begg⁸⁸ have published a description of their extensive and careful study on the problem of ruptured intervertebral disk in the lumbar region of the spine The results of routine myelography, done on patients suffering from low back pain, or sciatica, and admitted to the hospital because of severity or intractability of their symptoms, indicate that almost all such patients have intraspinal lumbar disk protrusion A protruded disk may cause only low back pain, presumably through implication of the sinu-vertebral nerve However, sciatica itself is produced only when the disk prolapse is so situated that it impinges upon a nerve root in its extrathecal course at the level of either of the lower lumbar vertebral disks Secondary changes, probably on the basis of intraneural edema, appear within the affected nerve root, contributing to production of symptoms by pulling the nerve root tightly against the prolapsed disk and thus causing an angulating strain In this manner pain fibers may be excited, and a

block in neural conduction may be produced, thus accounting for certain of the sensory, motor and reflex disturbances seen in this condition Resolution of these intraneural changes may result in spontaneous remission of clinical symptoms It is interesting to note that in Falconer's series spontaneous remission of symptoms occurred in patients at a time when a prolapsed disk was still demonstrable by myelography

CASE 35061

PRESENTATION OF CASE

A seventy-one-year-old unmarried woman entered the Tumor Clinic complaining of episodes of bloating and vomiting.

During the three months before admission to the Tumor Clinic she had experienced bouts of bloating, with nausea and vomiting, precipitated by food or drink. These episodes lasted only about one day and recurred on the average of once every three weeks. At the onset of the difficulty she had also noticed a feeling of pressure on the bladder, associated with urinary incontinence. About thirty years before admission she noticed moderate painless hematuria. About ten years later a suprapubic operation was done, and a "small growth" was removed. Her physician informed her that there would be a tendency for the tumor to recur, and she returned for many transurethral treatments for the purpose of cutting down the tumor. About sixteen years before admission she was told that the right ureter was closed. Operation was performed, and the ureter opened. It was kept dilated by cystoscopies and passages of ureteral sounds at weekly intervals and later less frequently. About three years before entry to this hospital, following an episode of hematuria, she entered another hospital, where two papillomatous tumors were removed from the bladder by suprapubic operation. At that time no function of the right kidney was demonstrable by intravenous pyelogram. About ten months later she re-entered the same hospital, complaining of a "lump" in the right side. A right nephrectomy and ureterectomy were done. The pathological report was "papillary carcinoma of pelvis and kidney."

Examination in the Tumor Clinic revealed an incisional hernia of the lower mid-abdomen and a firm, movable mass, about the size of a grapefruit, which could be ballotted between the abdominal and pelvic examining fingers on vaginal examination. On barium enema there was a large, extrinsic, tumor mass that displaced the rectum and lower sigmoid to the left. On intravenous pye-

lography the left kidney showed a slight dilatation of the calyces and pelvis, the right kidney was not visualized. The mass in the pelvis had displaced the left ureter laterally, and there was questionable slight compression of the lower third of the left ureter. It also depressed the roof of the bladder. There was generalized osteoporosis of the bones of the lumbar spine and pelvis but no definite evidence of metastases. A chest film showed clear lungs. The heart was slightly prominent in the region of the left ventricle. A gastrointestinal series was negative except for a moderately large, easily reducible hiatus hernia. She was followed in the Tumor Clinic for about two months and then admitted to the hospital.

Physical examination revealed a thin woman. Abdominal examination disclosed a large, "cystic-feeling," movable, multilobular mass, apparently arising from the pelvis. On pelvic examination a mass was felt in the cul-de-sac, apparently connected with the abdominal mass.

The temperature was 99.8°F, the pulse 96, and the respirations 22. The blood pressure was 208 systolic, 90 diastolic.

Examination of the blood showed 12.2 gm. of hemoglobin and a white-cell count of 7500. The urine specific gravity was 1.004. The sediment contained 30 to 40 white cells per high-power field. The serum nonprotein nitrogen was 31 mg., and the total protein 6.3 gm. per 100 cc. The chloride was 106 milliequiv. per liter, and the prothrombin time was 22 seconds (normal, 16 seconds). A phenolsulfonphthalein test showed 40 per cent excretion of the dye in ninety minutes. An intravenous pyelogram, repeated about two and a half months after the one done in the Tumor Clinic, showed poor concentration of the dye. There was marked dilatation of the calyces and pelvis. Only the upper third of the left ureter was seen, and this was dilated. The bladder was depressed but showed no definite defects. The mass in the pelvis had tripled in size since the time of the previous examination. A cystoscopy showed that only a third of the bladder mucosa could be visualized, no abnormalities were noted. The left ureteral orifice appeared normal. The mass in the pelvis so compressed the bladder that complete examination was not possible.

On the fifth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WYLAND F. LEADBETTER. We have several things to explain in this case: the episodes of vomiting, the mass in the pelvis, and the developing hydronephrosis and hydroureter on the left side. So far as the first part of the history is concerned, it seems quite obvious that for thirty years the patient suffered from recurrent tumors of the bladder. The type of tumor that might give rise

to recurrences without serious manifestations is a papillary tumor. It may have begun as a true papilloma of low-grade malignancy, or may have recurred as a papilloma or later as a papillary carcinoma. In any case, for fifteen of the thirty years she received treatment for recurrent bladder tumors.

Sixteen years before the last admission it was found that obstruction existed in the lower right ureter incident to either growth of the tumor or treatment thereof. I assume that as a result of the removal by fulguration or electroresection of one of the tumors the right ureteral orifice became scarred and ultimately closed. Operation was carried out to correct this obstruction, and the result must have been fairly satisfactory because up to three years before this admission cystoscopy was done at gradually increasing intervals for dilatation of the ureter. Hematuria recurred at this time, and the patient was found again to have a papillary tumor of the bladder. This one was removed by suprapubic operation. At that time no function was demonstrated in the right kidney. This brings up the point that many papillary tumors of the urinary tract may have their origin in the renal pelvis or ureter with secondary involvement of the bladder. Whether bladder tumors under these circumstances arise independently as a result of some carcinogen excreted in the urine or by implantation of tumor cells on the bladder mucosa from the renal pelvis or ureter, I do not know. In any case, we have found from experience that if we are dealing with a papillary tumor of the bladder we must at least obtain an intravenous urogram to determine whether there is evidence of tumor in the upper urinary tract. In a significant number of cases we find associated papillary tumor of the renal pelvis or ureter. In the case under discussion there was a papillary tumor of the right renal pelvis or ureter, because two years before the patient entered this hospital a nephroureterectomy was done. The record states that a "papillary carcinoma of the pelvis and kidney" was found. It would be interesting to know whether the ureter was involved because it might have a bearing on subsequent events. If transection of the ureter occurred through tumor, or if tumor cells from the ureter were spilled, it is possible that a recurrence of papillary carcinoma took place outside the bladder wall in the pelvic tissues. Up to this point in the case we can be quite certain of the state of affairs.

When the patient came to the Tumor Clinic it was found that she had a firm, movable mass about the size of a grapefruit in the pelvis. This could be palpated easily on combined abdominal and vaginal examination. It implies that the tumor was not deeply infiltrating or fixed to the pelvic wall. There is no statement referable to the pelvic organs, which is unfortunate because there is no way of knowing whether there was disease of the uterus or adnexa.

It therefore seems impossible to make a definite diagnosis.

DR TRACY B MALLORY: Can you give us any further information on that point, Dr Sturgis?

DR SOMERS H STURGIS: No. I just saw her on entry to the hospital two months later.

DR LEADBETTER: I think one can assume that this mass did not suggest disease of the cervix. I do not think we can carry it any farther than that. A barium enema showed nothing in the lower bowel. Intravenous pyelograms showed dilatation of the left renal pelvis and ureter. There could have been intrinsic disease of the left lower ureter or pressure on the ureter by the mass in the pelvis. A mass of this size would cause pressure on and distortion of the bladder.

There was generalized osteoporosis of the bones of the lumbar spine and pelvis, but no definite evidence of metastasis. I do not like the statement "no definite evidence." It implies to one reading the record that the radiologist was suspicious of metastatic disease in the bone but unwilling to commit himself. The chest films were normal. A gastrointestinal series was negative except for hiatus hernia, which probably has no bearing on our problem. In the two months that intervened between examination in the Tumor Clinic and entry to the hospital, the pelvic mass changed markedly in size, consistence and configuration. What happened during the two-month interval is difficult to say. If we are dealing with cancer, necrosis or hemorrhage or both may have occurred, or the tumor itself may have simply grown tremendously.

The presence of white cells in the urine is not significant since it is improbable that cystoscopic treatment could have been repeatedly carried out for thirty years without some infection being present. One is obliged to make the diagnosis of cystitis, and possibly, of low-grade pyelonephritis of the left kidney. The nonprotein-nitrogen was normal but the phenolsulfonephthalein test showed diminished excretion in ninety minutes. An intravenous urogram showed poor function, with dilatation of the pelvis and ureter, which had increased a great deal in two months. Cystoscopy was reported to allow incomplete visualization of the bladder interior, but no abnormalities were noted.

The question of tumor involving the bladder wall comes up, and with the information at hand it is difficult to be sure that such a tumor was not present. It is a possibility. In view of the dilatation of the left upper urinary tract, it would be desirable to know whether intrinsic disease of the left lower ureter existed. It could have been determined by ureterogram. I would not have wanted to operate without knowing something more about this.

From the standpoint of diagnosis my explanation seems too easy to be true and there is probably some catch, but I think the most likely possibility is that

recurrent papillary carcinoma developed outside the bladder wall in the tissues behind the bladder, either from spillage of cells at the time of ureterectomy or from tumor cells in the intramural ureter, which may not have been removed. If we knew the condition of the pelvic organs prior to the development of the mass, diagnosis would be much easier.

For the sake of completeness we have to consider other possibilities. Since papillary tumors of the bladder had been repeatedly treated, it is possible that extension through the bladder wall occurred, even though the bladder lumen showed no evidence of tumor. Involvement of lymphatics in the pelvis is possible. The mass may have originated in the iliac or hypogastric glands, but the description of the mass as ballotable leads one to believe that it did not arise in the pelvic wall itself. It could have been, I suppose, an ovarian neoplasm or a mass in the fundus of the uterus. We have to consider the sigmoid as the point of origin in spite of the normal barium enema — cancer of the bowel or an abscess arising in an infected diverticulum of the sigmoid. These possibilities seem very unlikely. A diverticulum of the bladder, with a very tiny communication with the bladder, and a perivesical abscess originating in infection at the time of operation two years before, are remote possibilities. Lymphosarcoma, retrovesical sarcoma or sarcoma arising in the bladder wall are mentioned but excluded because of the lack of fixation of the mass. A ruptured aneurysm of a pelvic vessel is dismissed as extremely unlikely.

DR F DENNETTE ADAMS: Would you expect carcinoma — that is, recurrent carcinoma — to be as movable as this mass was?

DR LEADBETTER: Papillary carcinoma may not be a markedly infiltrating tumor. It may form a mass without extreme fixation.

DR LANGDON PARSONS: How often do tumors of the genitourinary tract metastasize to the ovary?

DR LEADBETTER: I have never seen it, but in going over a series of 100 cases of bladder cancer autopsied at the Johns Hopkins Hospital, I believe I found 2 or 3 cases metastasizing to the ovary.

DR JOE V MEIGS: A Krukenberg tumor of the ovary may come from a tumor of the stomach, uterus, bile ducts or rectum, but I never remember it from the kidney or ureter. I think it could happen.

DR LEADBETTER: I should have mentioned the possibility of carcinoma of the gastrointestinal tract with peritoneal implant in the cul-de-sac.

DR MEIGS: There was no blood in the urine to any extent, which might be odd if the tumor extended directly from the bladder to the pelvic wall.

DR LEADBETTER: Yes.

May we see the x-ray films?

DR STANLEY M WYMAN: The lung fields are clear. The heart is definitely enlarged, but with-

out characteristic configuration. The barium enema outlines an ill defined, soft-tissue mass occupying most of the pelvis centrally, displacing the sigmoid and rectum toward the left, but it does not appear to involve the colon intrinsically. The first pyelogram shows prompt excretion of dye by the left kidney, with blunting of the minor calyces, slight widening of the major calyces and definite displacement of the left midureter. The left ureter can be seen on a later film, displaced far to the left. In the left pelvis the bladder shadow shows some compression laterally. Again the outlines of the mass in the pelvis are indistinct. There is no unusual calcification or rarefaction. Examination done about two months later shows a definite increase in the size of the pelvic mass, which now rises out of the pelvis. The left kidney is seen to be tremendously increased in its degree of hydronephrosis. The left ureter can be followed only for a short distance. Examination of the stomach shows a hiatus hernia as described. The available films fail to reveal any definite intrinsic disease of the stomach itself. There is some suggestion of poor filling of the medial aspect of the duodenal loop, but I can make no further statement about that.

DR LEADBETTER: On viewing the x-ray films, I must say that the mass is larger and growing more rapidly than I had supposed from reading the record. It suggests that the lesion was a cystic tumor arising from the pelvic structures, probably the ovary. I have to retract my impression of recurrent carcinoma originating in the urinary tract.

CLINICAL DIAGNOSIS

Malignant ovarian cyst

DR LEADBETTER'S DIAGNOSES

Cystic ovarian tumor

Hydronephrosis and hydroureter, left

Chronic cystitis

ANATOMICAL DIAGNOSIS

Metastasis of papillary carcinoma of bladder to ovary

PATHOLOGICAL DISCUSSION

DR STURGIS: When this woman came into the hospital she had this tremendous tumor, filling the whole pelvis. It was somewhat fixed on the right side. We thought she had an ovarian cyst, probably malignant. This is why we operated, but I cannot explain the tripling in size during the short period of observation. We found that she had an ovarian cystic tumor definitely arising from the right ovary. It was very large, and in bringing it up we ruptured it. It was filled with dark, chocolate material, and was a papillary type of malignant growth in the ovary. The patient was seventy-one years old and had only one kidney, and because of the fear of spillage we did not do

more than remove the right ovary and closed her up. The uterus was tiny and atrophic. We believed that we were not justified in prolonging the operation for the sake of more accurate diagnosis.

DR MALLORY: The mass that reached the laboratory looked like an ordinary papillary serous cystadenoma of the ovary, on gross examination there was no question of what it was. On microscopical examination we found that the entire mass was lined with characteristic transitional epithelium, it looked exactly like a bladder papilloma, and I think, without doubt, it represented metastasis to the ovary, from a primary bladder or ureteral tumor. The tumor cells were those of a low-grade type of papillary carcinoma.

DR LEADBETTER: Why did the mass increase in size so rapidly? Because of hemorrhage?

DR MALLORY: The cyst contained a large amount of fluid, and there had been hemorrhage into it.

DR STURGIS: That is what we thought.

DR MEIGS: Could it not have started in a dermoid type of teratoma that contained a transitional type of epithelium rather than as a metastatic lesion?

DR MALLORY: I do not believe so. If I gave you a section of the wall of the ovary, I think you would, without hesitation, say that it was a characteristic bladder tumor. Whether or not the ovary was previously cystic, I do not know. It is possible that the metastasis occurred into an already cystic ovary. I cannot answer that.

DR MEIGS: Frequently tissue in the ovarian dermoid or teratoma resembles tissue from other parts of the body that can grow. We often see tumors that resemble the thyroid gland. We see intestinal or endocervical mucosa from which a pseudomucinous cystadenoma arises, so why cannot that kind of epithelium be found in a dermoid?

DR MALLORY: In theory any type of tissue may develop in a teratoma, in practice I have never seen an ovarian cyst with this type of lining. The only type of ovarian tumor containing transitional epithelium is a Brenner tumor, that has a different appearance.

DR MEIGS: And a Brenner tumor can also be associated with dermoid, can it not?

DR MALLORY: I have never heard of a Brenner tumor becoming malignant, however.

DR MEIGS: I have not either.

DR PARSONS: Was there any bone element?

DR MALLORY: We found none.

CASE 35062

PRESENTATION OF CASE

First admission. A fifty-three-year-old housewife was admitted to the hospital because of "asthma and exhaustion."

Before the age of forty the patient experienced occasional episodes of mild wheezing and dyspnea

with exertion. These were not particularly troublesome and were attributed to obesity. When she was forty she had rather severe "asthmatic attacks," which disappeared spontaneously after a few days. Since that time she had almost continuous year-around attacks, which could not be related to place or season. Three years before admission she was studied in another hospital, where she was said to have been allergic to goats, feathers and chocolate. She stated that the attacks became worse upon contact with these substances. Episodes of nervousness and tension also increased the symptoms, and because an active social life tended to aggravate her condition she had recently lived a rather secluded life. The last severe attack began about two months prior to admission at which time she was admitted to another hospital, where she gained some relief.

The patient's general health had "always been poor." An attack of rheumatic fever when she was seven was followed by sore throats three or four times yearly until the age of thirty-five, when a tonsillectomy was done. She had suffered frequent attacks of sinusitis, for which she was operated upon twice. During one period she took desiccated thyroid for obesity and developed marked tachycardia, nervousness and tremor. She had suffered bouts of diarrhea, lasting three or four days, coming on every three or four weeks, for the past four years. There was no history of chest pain or ankle edema.

Physical examination revealed a well developed and well nourished woman with slight asthmatic breathing. The neck veins were not distended, and the chest was symmetrical with increased anteroposterior diameters. There was moderate emphysema, with decreased fremitus and hyperresonance. There was questionable wheezing on the right side anteriorly. The point of maximal impulse was 1 cm beyond the midclavicular line, and a Grade I systolic murmur could be heard at the apex. The rhythm was normal, and the pulmonic second sound was not loud. The liver edge was felt 1 cm below the costal margin.

The temperature was 99.5°F, the pulse 115, and the respirations 24. The blood pressure was 140 systolic, 60 diastolic.

The urine was normal. The blood hemoglobin was 16 gm, the white-cell count was 8000, with 76 per cent neutrophils. The blood sugar was 116 mg, the nonprotein nitrogen 11 mg, and the total protein 4.4 gm per 100 cc. A roentgenogram of the chest disclosed fairly large lung fields, with some increased density posteriorly in the costophrenic angle. The diaphragm was low in position and showed some limitation of motion. The heart was in the upper limits of normal in size. Many scratch tests, including those for feathers and goats, were negative.

The patient continued to have dyspnea and spells of coughing. There was cyanosis of the lips and nail beds. On the eleventh hospital day the blood hemoglobin was 14.4 gm, and the total protein 5.02 gm per 100 cc, with an albumin-globulin ratio of 1.6. The blood sodium was 138.1 and the chloride 95 milliequiv per liter, the nonprotein nitrogen was 19 mg per 100 cc. On the seventeenth hospital day a "sore throat" developed, following which orthopnea and wheezing became worse. When sitting up in bed she was cyanotic, but upon lying flat much of this disappeared. The neck veins were distended, and there were rales in the chest. She was given several injections of mercurhydrin, after which she showed slow but steady improvement. She was discharged on the thirtieth hospital day.

Final admission (approximately three weeks later). In the interval the patient experienced little dyspnea or wheezing, although she remained in bed most of the time. One week before entry, however, she noticed swelling of the ankles and abdomen, although orthopnea and breathing were no worse. She was given several injections of mercurials to no avail.

On physical examination the patient breathed somewhat heavily but without audible wheeze. There was no cyanosis, the neck veins were distended. There were rales in both bases, and the heart findings were essentially the same as on the previous admission. The liver edge was palpated four fingerbreadths below the costal margin, with tenderness in the right upper quadrant. There was a +++ pitting edema of the ankles and ++ edema over the sacrum.

The temperature was 98°F, the pulse 90, and the respirations 20. The blood pressure was 120 systolic, 60 diastolic.

The urine gave a + test for albumin. The blood hemoglobin was 13 gm, the white-cell count was 9400, with 73 per cent neutrophils. The blood sugar was 148 mg, and the cholesterol 231 mg per 100 cc.

The patient's condition did not improve. She refused to eat a salt-free diet. A roentgenogram showed a suggestion of fluid in the right costophrenic sinus, and the heart shadow appeared slightly larger than before, the enlargement appearing to be chiefly in the region of the left ventricle. An electrocardiogram showed sinus tachycardia at a rate of 100, with a PR interval equal to 0.15 second. There was moderate right-axis deviation and a tendency toward low voltage in all limb leads. There was a low and upright T wave in Lead 1, depressed ST segments with diphasic T wave in Leads 2 and 3. The T waves were diphasic in Lead VR, low and upright in Lead VL, diphasic in VF and upright in V₁, V₄ and V₆. The ST segments were depressed in Lead VF.

On the fourth hospital day the blood sodium was 135.2 and the chloride 83 milliequiv per liter. Four days later the blood carbon dioxide was 44.1 milliequiv per liter. On the eleventh hospital day the red-cell count was 5,810,000, the hemoglobin 13.6 gm and the pH 7.35. The patient became progressively more cyanotic but with little orthopnea. There were rales in the right base but normal breath sounds. There was +++ edema of the lower extremities, and ++ edema over the abdominal wall. The abdomen was distended, and shifting dullness was present. On the sixteenth hospital day the serum protein was 6 gm per 100 cc, and the potassium 5.4, the sodium 138.8 and the chloride 83 milliequiv per liter. She was given mercurial diuretics intermittently, with irregular response. Oxygen relieved much of the cyanosis. During the following several weeks periods of improvement alternated with periods of relapse, although the course was progressively downhill. On the forty-fifth hospital day the patient began fibrillating, the temperature, pulse and respirations rose, and two days later she died.

DIFFERENTIAL DIAGNOSIS

DR J. EVARTS GREENE. This patient is said to have had occasional episodes of mild asthma or at least mild wheezing and dyspnea on exertion before the age of forty. There is no record of such symptoms without exertion, they were attributed to obesity, but it is possible that they were due to early emphysema or low-grade chronic bronchitis. When she was forty she had what was described as a severe asthmatic attack, and thereafter she had asthma the year round without relation to place or season. Forty years of age is the time, as Dr Rackemann has frequently emphasized, when intrinsic asthma begins to be much more frequently noted than extrinsic. I think the fact that she had her symptoms all year round, without relation to season or place, but increased by nervous tension, is in favor of a diagnosis of intrinsic asthma. She may have had minor allergies, but they certainly did not play an important part in her final illness. Her general health was always poor. She had early rheumatic fever, many sore throats and attacks of sinusitis. I cannot relate these conditions to the complaints that led to death. She is also said to have suffered from repeated diarrhea, apparently quite frequently, every three or four weeks.

I would like to ask if any stool specimens were examined for amebic cysts.

DR FRANCIS M. RACKEMANN. No.

DR GREENE. If the patient had amebic colitis, it could hardly have had any bearing on what happened later. On physical examination she had signs of emphysema and mild asthma. There was questionable wheezing on the right side. The liver edge was felt 1 cm below the costal margin. The blood

pressure was 140 systolic, 60 diastolic — certainly not a low pressure

The laboratory findings, except for moderately low total protein, do not seem remarkable. X-ray examination is said to have shown fairly large lung fields, with increased density posteriorly in the costophrenic angle. May we see the films?

DR STANLEY M. WYMAN: The films taken on the first examination show the density described in the posterior costophrenic sinuses, which I believe represents a small quantity of fluid in both pleural spaces. Increase in the anteroposterior chest diameter is quite well shown. The lung fields themselves seem rather large and somewhat bright for a patient of this size. The heart shadow is at the upper limits of normal, without definite characteristic configuration, however. I think we should add that the hilar vascular shadows are increased in prominence, and the proximal portions of the pulmonary artery in both lung fields are somewhat engorged. I cannot see any definite localized pulmonary disease, however.

Examination two months later shows a definite but small quantity of fluid in the right costophrenic sinus and possibly on the left. The heart shadow may be a little larger. This is not a very conclusive finding. The third examination has not, so far as I can see, changed materially. I think the statement that the left ventricle appeared to be large is wrong; I think this simply emphasizes to us once again that we cannot differentiate well left ventricular from right ventricular enlargement in the presence of engorged pulmonary vascular shadows. Right ventricular enlargement is more consistent with this picture.

DR GREENE: There is no evidence of pulmonary fibrosis?

DR WYMAN: We looked carefully for diffuse pulmonary fibrosis because we thought that this patient had cor pulmonale but were unable to be certain of diffuse fibrosis. I know that it can be completely missed on x-ray examination, however.

DR GREENE: Did you find anything suggesting calcification of the pericardium?

DR WYMAN: No, neither fluoroscopically nor on the films.

DR GREENE: The skin tests done here were apparently negative. The patient continued in the first hospitalization to have dyspnea and coughing, with cyanosis.

I do not think the blood chemical findings, except for the total protein, were significantly altered. On the seventeenth day the patient was said to have developed a "sore throat." I am not sure whether that means that no one could see an inflammatory process. At least orthopnea and wheezing became worse.

"While sitting in bed she was cyanotic, but upon lying flat much of this disappeared." I do not know what that statement signifies. I have seen an occa-

sional patient with emphysema who stated that he was a good deal more comfortable lying down than sitting up. Usually, such patients merely state that they are not more uncomfortable lying down than sitting up. On the other hand, the patient is said to have had orthopnea at this point, but why the cyanosis disappeared on lying down, I cannot say. During the interval between hospitalizations, swelling of the ankles progressively increased. On the second hospital admission the liver was markedly enlarged, and again the neck veins were distended but there was no cyanosis.

DR RACKEMANN: I do not think that is correct. As I recall, there was cyanosis all the time.

DR GREENE: The blood sugar was 148 mg per 100 cc, that is an isolated finding, and I am tempted to disregard it. The heart was more enlarged, and electrocardiographic findings seem consistent with right-sided failure. I would be interested in hearing the cardiologists say a word about the unipolar leads.

DR CONGER WILLIAMS: They do not add a thing, I have been over them, and they do not help at all.

DR GREENE: The carbon dioxide of 44 milliequiv per liter — a somewhat elevated figure — is consistent with emphysema. Patients with emphysema are supposed to have difficulty in eliminating carbon dioxide. During the second admission the red-cell count rose, consistent with passive congestion and emphysema. There was no definite acidosis, and the potassium was said to have been elevated. That is sometimes found in allergic episodes. I do not believe an acute allergic episode was involved at this stage of the game. It seems that the patient was going downhill slowly, with right-sided heart failure, and that she died for that reason.

In discussing the possible diagnoses we can dismiss the possibility of such conditions as nephrosis, amyloidosis and cirrhosis of the liver, which might cause swelling of the legs and abdomen, because they would not account for cyanosis or dyspnea. I think that asthma and pulmonary emphysema, followed by cor pulmonale, with right-sided heart failure and chronic passive congestion, would give a satisfactory explanation of this patient's illness. There is a possibility also, although it seems unlikely, that she had chronic constrictive pericarditis, which certainly could have caused the cyanosis and the swelling of the extremities and abdomen. However, as evidence against this, the patient apparently improved on mercurial diuretics, at least temporarily, she did not show any sign by x-ray study of pericardial thickening, and there was no history of antecedent illness to account for it. Ajerza's disease must be considered as a possibility, but I do not think we have enough definite data to make that diagnosis. Periarteritis nodosa is occasionally associated with asthma, but I cannot see that we have any definite reason to make a diagnosis of that condition. So I come back to my

The patient continued to have dyspnea and spells of coughing. There was cyanosis of the lips and nail beds. On the eleventh hospital day the blood hemoglobin was 14.4 gm, and the total protein 5.02 gm per 100 cc, with an albumin-globulin ratio of 1.6. The blood sodium was 138.1 and the chloride 95 milliequiv per liter, the nonprotein nitrogen was 19 mg per 100 cc. On the seventeenth hospital day a "sore throat" developed, following which orthopnea and wheezing became worse. When sitting up in bed she was cyanotic, but upon lying flat much of this disappeared. The neck veins were distended, and there were rales in the chest. She was given several injections of mercurhydrin, after which she showed slow but steady improvement. She was discharged on the thirtieth hospital day.

Final admission (approximately three weeks later)

In the interval the patient experienced little dyspnea or wheezing, although she remained in bed most of the time. One week before entry, however, she noticed swelling of the ankles and abdomen, although orthopnea and breathing were no worse. She was given several injections of mercurials to no avail.

On physical examination the patient breathed somewhat heavily but without audible wheeze. There was no cyanosis, the neck veins were distended. MEDICAL MONOPOLISTS

WHILE physicians argue among themselves over the most effective method by which their relations with the public can be improved, the lay public is being enlightened in a number of ways. One of the most recent is an article by J. D. Ratchiff in the *Woman's Home Companion* for October, 1948, that has been announced in full-page advertisements in various newspapers. With a foreword by Dr. Allen O. Whipple, former president of the American Board of Surgery, it exposes the "medical monopolists" who keep brilliant young doctors out of hospital staffs for fear of competition. For human interest it tells the story of "brilliant young Dr. Jim

Smith — straight A's" — and how he was "barred from practice in hundreds of communities by men with a fraction of his skill." The punch line is that so long as this deplorable situation goes unremedied, the community "will continue to get 1920 medicine for 1948 ills."

No exception can be taken to the article itself. Were it published to be read only by the medical profession it would amount simply to a necessary display of dirty linen in urgent need of washing. Directed to the lay public, however, and accompanied by an exhortation to "civic-minded individuals and organizations" to send for free reprints and then to "bring public opinion to bear," it becomes a subtle piece of propaganda in favor of state medicine. Its most effective feature is its omission of any reference to state medicine.

For who can doubt the direction in which such civic-minded public opinion would be directed? And on whom would the pressure be exerted? It would be "brought to bear" on the congressmen who are already considering bills for governmental control of the practice of medicine.

But is that the way to remedy this admittedly deplorable situation? By what laws have morals ever been successfully dictated? Deplorable economic and political situations exist about which the individual physician can do little or nothing — the high cost of medical care, the high price of medical education and the shortage of hospital beds, to mention only a few — but this "medical monopolist" situation is one piece of dirty linen that the medical profession should be able to wash for itself because it is essentially a moral situation. That the leaders in the profession are aware of its existence and are eager to put a stop to it is evident in the presidential address delivered last fall before the New England Surgical Society and published elsewhere in this issue of the *Journal*. Wherever it may exist it is a cynical betrayal of the public confidence, a brazen violation of the Hippocratic oath and a selfish denial of the basic purpose of the whole medical profession. A better punch line would have been wash day is here — if you doctors don't want to be taken to the cleaners by force, start washing!

first diagnosis of asthma, emphysema, cor pulmonale and right-sided heart failure

DR RACKEMANN We had quite a time with this patient. I do not think the history gives quite a true picture of what was going on. The attack that she had at the outside hospital before she came in here was quite obviously asthma. She came in here three months before she died. The low serum protein on the first admission was quite striking. The connection of this finding with her other symptoms was hard to determine, and what caused the cyanosis was hard to say. There was some asthma, — a little shortness of breath, — but it was not striking at that time. There was no evidence that I could see of any strain on the right side of the heart. However, the consultants, Drs Bland and Williams, showed that I was wrong — that the cyanosis could be interpreted on the basis of right-sided heart failure. She went home in fair shape. Three weeks later she came in again, and the picture was entirely different. The cyanosis was still present, but she had a full-blown picture of right-sided heart failure, with severe pitting edema of the extremities, fluid in the abdomen and soft, pitting edema of the abdominal wall. That bothered us a good deal. Why did she have edema? Why did she not improve with digitalis and mercurial and other diuretics? It was all very puzzling. The story of asthma did not seem severe enough to produce the strain on the right side of the heart, considering that so many people have the same story with no such terminal findings. Then, as we went on, it became clear that she could not get rid of the excessive carbon dioxide. The heart seemed normal, the pulse was regular, the rate being elevated to 100 or sometimes 110. Days and weeks went by, and very little change occurred in the *status quo*. Except for the continuous edema, the heart seemed to function reasonably well. So then we began to think about other reasons for obstruction of the blood flow from the right side of the heart, and that led us to lean toward the diagnosis of Ayerza's disease.

DR WILLIAMS I have little to add. I was interested in one thing — namely, that in several reported series of patients with cor pulmonale secondary to pulmonary asthma the patients had been entirely or predominantly of the male sex. I think it is a little unusual for someone to develop pulmonary fibrosis, or whatever one chooses to call this syndrome, in such an apparently short time on the basis of asthma alone. I do not see any other explanation for it, however.

DR DONALD S KING In the past we have not had to have changes in blood vessels, emphysema occurred alone with this much right-sided failure.

CLINICAL DIAGNOSES

Cor pulmonale
Pulmonary endarteritis
Ayerza's disease

DR GREENE'S DIAGNOSES

Bronchial asthma
Pulmonary emphysema
Chronic cor pulmonale
Right-sided heart failure

ANATOMICAL DIAGNOSES

Pulmonary emphysema
Pulmonary arteriosclerosis
Cor pulmonale
Terminal thrombosis of pulmonary arterioles
Acute central necrosis of liver
Adenocarcinoma of thyroid gland

PATHOLOGICAL DISCUSSION

DR TRACY B MALLORY Autopsy showed voluminous emphysematous lungs, with large blebs in them. The pulmonary vessels demonstrated numerous atheromatous plaques, and the small pulmonary arteries and arterioles contained thrombi very diffusely and extensively throughout the lung. These thrombi were rather friable and slightly adherent to the vessel wall. At the time of autopsy we thought they might show early organization. Microscopical sections failed to confirm that entirely. The thrombi must have been of quite recent origin — I should think certainly less than a week's duration, perhaps three to five days — so they can be regarded only as a terminal event. The heart weighed 420 gm, and the right ventricle was 9 mm in thickness, a marked grade of cor pulmonale. The liver showed an extreme degree of passive congestion, with acute terminal central necrosis, which, I think, was perhaps of the same duration as the acute process in the pulmonary arteries. There was an incidental finding — a markedly nodular thyroid gland, and one of the nodules showed early carcinomatosis. That had nothing to do with the symptomatology, however. From the anatomic point of view, the only diagnoses are emphysema, pulmonary arteriosclerosis, cor pulmonale and a terminal episode of acute thrombosis of the small pulmonary arteries. The picture was not what one ordinarily calls Ayerza's disease — long-standing apparently primary disease in the pulmonary arteries.

sity hospital. In New England the same joining of interests has taken place, but we do not have university hospitals as such, preferring to enjoy the obvious advantages without merging the identity of either institution into the other. Our arrangement calls for a little more understanding on the part of all concerned, but this is only a greater stimulus to co-operation and recognition of the common cause. As these centripetal forces continue, what are becoming known as medical centers are formed. In a modern medical center there appear to be not two, but three major interests: medical education and medical care find themselves in the presence of a third party, medical research. How to make elbow room for this new and essential interest has already become a problem in many centers.

At the New England Medical Center the solution of the problem was dedicated on November 11, 1948, at the formal opening of the Ziskind Research Laboratories. In a seven-story building 24,000 square feet of floor space are already equipped and in use, another 36,000 feet are ready to be equipped in the near future, and a total capacity of 96,000 square feet is available in the potential capacity of the building as a whole. The two floors now in use are connected by a bridge with the Joseph H. Pratt Diagnostic Hospital, which in turn is connected with the other units of the Center.

Mr. Jacob Ziskind's generosity has thus solved the problem of adequate physical facilities for research at this center for many years to come. But, as is so often the case and as was pointed out at the dedicatory exercises, the solution of one problem creates another, how may the research activities best fit themselves into the programs of medical care and medical education already underway? In discussing the necessity for careful integration of these elements it was stated that an effort would be made to have the staff fall into three broad categories: bedside clinicians, basic research scientists and a group who might be termed "clinical scientists." The clinical scientist would attempt to be conversant with the problems both of the bedside and of the laboratory. The center would then have to rely for its fullest development on the combined efforts of these three groups. With such a staff it is hoped that the smooth transition from the

laboratory to the bedside can develop. So the evolutionary processes go on.

POSTGRADUATE LECTURE COURSE

WITH the fourth annual postgraduate lecture course in general medicine impending, it is rapidly becoming a midwinter tradition to give it the usual journalistic introduction. There seems to be no reason why this course should not take equal rank with the better known of the various winter carnivals, perhaps even with New Orleans's famous Mardi Gras—less spectacular but still more instructive.

Arranged by the efficient and far-sighted Committee on Postgraduate Education of the Massachusetts Medical Society, the course will again be given in Sanders Theater, Harvard University, Cambridge. It will run, as usual, on Mondays from 6:00 to 9:00 and on Wednesdays from 4:00 to 6:00 p.m., beginning this year on Monday, March 7, and closing on Wednesday, April 27. An outline of the program is printed elsewhere in this issue of the *Journal*, and the full program will be published shortly.

A feature of the 1949 program will be the discussions planned for March 7, built around the subject of "A Positive Program for the Health of the Public." This program, on the "hottest" subject in medicine today, will be under the joint chairmanship of Dr. James S. Simmons, dean and professor of public health at the Harvard School of Public Health, and Dr. John F. Conlin, director of medical information and education of the Massachusetts Medical Society.

Participating will be Dr. Hugh R. Leavell on "Local Health Departments," Dr. Samuel B. Kirkwood on "Maternal and Child Health," Dr. Stuart S. Stevenson on "School Health," and Dr. Albert O. Seeler on "Industrial Health." All the speakers are from the Harvard School of Public Health.

The course is free to all physicians residing in New England, regardless of membership in any medical society. Those who wish to register immediately for the course should do so by writing to the Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston.

THE THERAPEUTIC ROLE OF THE KEMPNER DIET

DIETARY restriction of one sort or another has been utilized in the treatment of hypertensive disease for many years. In 1945 Kempner¹ presented the details of his commendably aggressive approach to the dietary treatment of this group of diseases and thereby stirred up a great deal of comment, both medical and lay. Kempner's own therapeutic results are little short of miraculous and have justifiably impressed numerous competent and critical observers who have visited the North Carolina clinic. Investigators other than Kempner have obtained favorable, but not miraculous, results in most cases, and the chief difficulty seems to center around the extreme monotony of the diet. Most physicians lack the extraordinarily persuasive powers required to keep a patient eating rice and certain types of fruit for weeks, months or even indefinitely. The usual result is that the patient fails to eat all the food presented to him and, not infrequently, finally rejects the diet altogether.

Kempner's claim that patients following his regimen remain in nitrogen balance is adequately refuted by recent balance studies.² Regarding maintenance of weight on the Kempner diet there is further disagreement between Kempner and other workers. Kempner finds that patients receiving the diet lose weight initially but after some weeks the weight becomes stable and all is well—in fact, so well that the diet can often be modified slightly. He attributes the initial loss of weight to loss of fluid. It has proved very difficult for other investigators to confirm or deny these claims, mainly because so many patients cannot conform to the rigid requirements of the Kempner regimen over long periods. It seems clear, however, that patients receiving the Kempner regimen in clinics other than Kempner's own lose not only fluid but also body tissue. The diet, as it usually works out in practice, is a specialized sort of starvation ration, and the contention that it is adequate in calories and protein needs modification.

It is entirely possible that the tendency for patients on the Kempner regimen to eat less than the stipulated amounts of rice and fruit can be used to advantage in certain types of cardiac disease with

failure. Salt restriction in such patients is unquestionably highly important. Reduction in weight over and above that due to fluid accumulation is crucial in many obese patients with cardiac failure. Heretofore the patient has been offered a low-calorie diet, which often supplies 800 calories or less, to achieve loss of body tissue. He has been implored and cajoled not to eat more than the allowed amount, in spite of which he often reaches a point where he secretly takes extra food and the physician cannot understand why the patient's weight remains too high. The psychologic, as well as the physiologic, advantages of the Kempner regimen in this situation seem not to have been appreciated. Using the rice-fruit diet, the physician, instead of pleading with his patient to eat less, actually has to urge the patient to eat all the food given him. The very low salt intake, a difficult feature to control on any sort of hospital diet other than that devised by Kempner, helps to rid the patient of excessive fluid, and concurrently, the usual inability to maintain the caloric intake allowed by the Kempner regimen causes a reduction in body fat and protein. Practically speaking, there probably is no more effective diet for obese decompensated cardiac patients.

Although the Kempner regimen is certainly not the final answer in the treatment of hypertensive disease, it is an important development in the search for a practical and uniformly successful method of treating the disorder. Furthermore, it may well find a permanent place in the treatment of some types of congestive cardiac failure and even in uncomplicated obesity.

THE ZISKIND RESEARCH LABORATORIES

DURING the past quarter century the evolution of medical knowledge has brought into action a centripetal force that crowds together groups of interests and activities formerly carried on as separate endeavors. Medical education and medical care were the first to merge, and their common interests have produced in many parts of the nation a type of institution aptly described as the univer-

Attention is called to the fact that this is *not* a diagnostic test. Information about the type will not become available until the patient is in the convalescent stage.

The determination of the virus etiology depends upon demonstrating a rise in titer of antibodies against the virus of either influenza A or influenza B. To demonstrate this rise in titer, it will be necessary to have two specimens of blood; one taken during the acute illness and the other taken two weeks later. No examination will be made of the first specimen unless the second specimen is received.

The Diagnostic Laboratory will be able to handle a reasonable number of specimens. Facilities are not available for examining an unlimited number. This is not necessary, of course, since it is an exception to the rule to have more than one virus highly prevalent in an area at one time. A few identifications of the type present in an area are all that are needed.

Special forms that should be used when blood specimens for serologic tests for influenza are sent in can be obtained by application to the Diagnostic Laboratory, 281 South Street, Jamaica Plain 30, Massachusetts.

MISCELLANY

INSURANCE FOR ALCOHOLICS

A survey to determine the stand insurance companies take on the insurability of applicants who have an alcoholic background is being conducted by the Keeley Institute of Dwight, Illinois.

Insurance companies, for the most part, turn down many applicants who have an alcoholic background, but who would otherwise be excellent risks, most of those rejected being actually alcoholics who have insight enough to recognize their condition and who have honesty enough to admit it. As with other ailments, such as diabetes, self-knowledge of alcoholism is of value in protecting the risk.

HAROFÉ HAFRI

With the appearance of Volume II, 1948, *The Hebrew Medical Journal*, under the editorship of Moses Einhorn, M.D., concludes its twenty-first year of publication.

In publishing *Harofé Hafri* semiannually, the editors have met the need for a medical journal written in Hebrew, with English summaries, thus aiding greatly in the advance and development of Hebrew medical literature.

AMERICAN HEART ASSOCIATION

Dr. John W. Ferree has been named director of the Public Health Division of the American Heart Association according to a recent announcement. Dr. Ferree will direct the development of public-health programs for the American Heart Association and will assist local heart associations in expanding and maintaining effective cardiac services in communities throughout the United States. He will supervise the Association's field staff now engaged in community organization and program development.

The formation of additional affiliated heart associations and the expansion of community services comprise an important objective of the American Heart Association's 1949 national campaign, from February 7 to 28, in which a total of \$5,000,000 is being sought for a three-way program of research, education and community service.

CORRESPONDENCE

REGARDING EXTRARENAL AZOTEMIA

To the Editor: I have read with much interest the article by Appel and Townsend entitled "Extrarenal Azotemia: Report of a severe case with recovery" in the January 20 issue of the *Journal*. The case reported therein would, I think, fit very nicely a diagnosis of lower-nephron nephrosis with spontaneous recovery. More specifically, the patient had severe oliguria for about ten days, followed by a diuresis (he was excreting over a liter of urine by the second hospital day); he had a marked azotemia, and examination of the urine showed red cells, white cells and casts in the sediment. The vomiting (with loss of hydrochloric acid) and the voluntary reduction of fluid intake during the oliguric period may well account for the alkalosis and for the failure to form edema respectively. The case would fit quite well into the series of lower-nephron nephroses with spontaneous recovery reported by Strauss in the November 4 issue of the *Journal*.

WALTER HOLLANDER, JR.

338 Vanderbilt Hall
Longwood Avenue
Boston 15, Massachusetts

Mr. Hollander's letter was referred to Dr. James H. Townsend, senior author of the article in question, who made the following reply:

To the Editor: The point raised by Mr. Hollander is a good one. In the absence of any histologic examination, of course, we cannot say whether there may have been morphologic changes in the kidney. Because of the very slight changes in the urine and the promptness of the recovery following administration of salt and water we believed that there was little if any actual disease in the kidney.

The distinction between "extrarenal azotemia" and lower-nephron nephrosis, I think, is very largely an academic one. In this case there had been no condition leading to shock or severe anoxia or any other dramatic episode to cause a nephrosis. We chose to call the disease extrarenal azotemia. If Mr. Hollander chooses to call it lower-nephron nephrosis I should not object. The point is that this patient presented a severe picture resembling uremia that might well have been fatal and was very easily corrected by the simple administration of salt and water. He showed no evidence of any previous or permanent renal damage.

I have recently seen a somewhat similar case in another hospital that proved fatal and in which the kidneys showed no demonstrable lesion whatever. The patient was a catatonic schizophrenic who became extremely overactive and dehydrated and went into shock with azotemia and died.

JAMES H. TOWNSEND, M.D.

Mount Auburn Hospital
Cambridge, Massachusetts

NOTICES

ANNOUNCEMENTS

Dr. Sidney S. Gellis announces the removal of his office from 319 Longwood Avenue, Boston, to the Children's Hospital, 300 Longwood Avenue, Boston, for the practice of pediatrics.

Dr. Harold I. Shuman announces the removal of his office from 433 Beacon Street, Boston, to 92 Broadway, Taunton, for the practice of pediatrics.

Dr. Richard H. Wright announces the opening of his office for the practice of internal medicine at 1180 Beacon Street, Brookline.

SOUTH END MEDICAL CLUB

A regular luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston on Tuesday, February 15, at 12 noon. Dr. George W. Thorn will speak on the subject "Screening Tests for Adrenal Insufficiency."

All physicians are cordially invited to attend.

BOSTON MEDICAL LIBRARY

PERSONNEL

Mr Charles C Colby, III, joined the Library staff the first of the year as reference librarian, succeeding Miss Catherine Binderup. Mr Colby has an excellent background for the position, with the degree of A B from Harvard University in the field of biology (1943) and S B from Simmons College Library School (1947). He has had one year of a premedical course at Yale University and half a year in the basic medical sciences at Harvard Medical School. From the time of his graduation from Simmons College in June, 1947, until the end of 1948 he was employed as a cataloger at the Army Medical Library in Washington.

EXHIBITS

Concurrently with the meeting of the American Numismatic Society held in Boston in 1948, an exhibit of medals and coins of medical significance dating from the Roman period to modern times was placed in the rotunda at the Library. Through the courtesy of Dr Elliott P Joslin, the two diabetes medals awarded to survivors of the disease over long periods by the George F Baker Clinic were also displayed. Dr Paul Mueller, who recently received the Nobel prize for his discovery of DDT, was the subject of another exhibit, which included his portrait, his original article on his investigations, a sample of the insecticide and other material.

IMPORTANT ACCESSIONS

The Library is interested in the work of René Descartes, especially in the fields of knowledge related to medicine. The Library recently had the opportunity of obtaining a good, small collection of his publications, including the definitive edition of his collected works, published under the auspices of the minister of public instruction of the French Republic in twelve volumes (Paris, 1897-1910). This edition was reserved primarily for French libraries and institutions and is consequently a scarce set outside France. Unfortunately, it is printed on very poor paper that will not survive the ravages of use and time. There are also the *Opera philosophica* (Frankfurt, 1792-1797) in three volumes, and the *Oeuvres*, published by Victor Cousin (Paris, 1824-1826) in eleven volumes and an atlas. The Library already owned three early editions of *De homine*.

The reference division has been enriched by the acquisition of the Edwards reprint of the British Museum Catalogue, an essential tool for medical bibliographical research.

NEW PERIODICALS

The following sets have been added to the periodical division

American Journal of Orthopsychiatry (Menasha)
Vol 8 to date. The Library needs Vol 1 to 7 to complete this important set.
Folia cardiologica (Milan)
Helvetica medica acta (Basel)
Revista Espanola de cirugia (Madrid)
Revue d'hématologie (Paris)
Revista do Instituto Adolfo Lutz (São Paulo)

The Library has subscribed to the complete series of the *Excerpta medica*.

MASSACHUSETTS DEPARTMENT
OF PUBLIC HEALTHEND OF DISTRIBUTION OF DRIED
PLASMA BY RED CROSS

Dr Harry Kleinschmidt, director of health services of the North Atlantic Area of the American National Red Cross, has notified Dr Vlado A. Getting, commissioner of health for Massachusetts, that no further shipments of surplus dried plasma will be made after December 31, 1948. The supply of dried plasma turned over to the Red Cross after VJ Day is now reported to be so low that nationwide distribution cannot be continued. Dr Kleinschmidt expressed the hope that sufficient whole blood would be collected by the National Red Cross Blood Program to provide whole blood, plasma and fractions for the entire country.

Distribution of this plasma in Massachusetts during the past two years has been effected through the Division of Biologic Laboratories, 375 South Street, Jamaica Plain, Boston. At the present rate of distribution, the residual supply on hand at the Jamaica Plain depot will last until April 1, 1949. Hospitals are urged to conserve the plasma as much as possible until the Red Cross Blood Program is able to replace it with new material.

SEROLOGIC TESTS ON CONVALESCENTS
FROM INFLUENZA

The Department is co-operating with the National Influenza Information Center by attempting to determine the type of influenza virus present whenever the disease becomes prevalent. The Department is asking the co-operation of physicians in all parts of the Commonwealth in sending in acute and convalescent blood specimens on a small representative sample of the most suspicious cases occurring in an area where the disease appears to be prevalent.

Attention is called to the fact that this is *not a diagnostic test*. Information about the type will not become available until the patient is in the *convalescent stage*.

The determination of the virus etiology depends upon demonstrating a *rise in titer* of antibodies against the virus of either influenza A or influenza B. To demonstrate this rise in titer, it will be necessary to have *two specimens* of blood, one taken during the *acute illness* and the other taken *two weeks later*. *No examination* will be made of the *first specimen* unless the second specimen is received.

The Diagnostic Laboratory will be able to handle a *reasonable number* of specimens. Facilities are not available for examining an unlimited number. This is not necessary, of course, since it is an *exception* to the rule to have *more than one virus* highly prevalent in an area at one time. A few identifications of the type present in an area are all that are needed.

Special forms that should be used when blood specimens for serologic tests for influenza are sent in can be obtained by application to the Diagnostic Laboratory, 281 South Street, Jamaica Plain 30, Massachusetts.

Dr. Harold I. Shuman announces the removal of his office from 483 Beacon Street, Boston, to 92 Broadway, Taunton, for the practice of pediatrics.

Dr. Richard H. Wright announces the opening of his office for the practice of internal medicine at 1180 Beacon Street, Brookline.

SOUTH END MEDICAL CLUB

A regular luncheon meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, February 15, at 12 noon. Dr. George W. Thorn will speak on the subject "Screening Tests for Adrenal Insufficiency."

All physicians are cordially invited to attend.

NORFOLK DISTRICT MEDICAL SOCIETY

A meeting of the Norfolk District Medical Society will be held at the Boston Medical Library, 8 Fenway, Boston, on Wednesday, February 23, at 8 p.m. The scientific program, entitled "Symposium on Thromboembolic Disease," will be as follows:

Physiologic Aspects of Intravascular Thrombosis William C. Moloney, M.D.

Clinical Aspects of Anticoagulant Therapy James A. Evans, M.D.

Surgical Aspects of Thromboembolic Disease E. Everett O'Neil, M.D.

All physicians are invited

NORFOLK DISTRICT WOMEN'S AUXILIARY

The Women's Auxiliary of the Norfolk District Medical Society will meet in the State Suite at the Copley Plaza Hotel, Boston, on February 28, at 2:30 p.m.

BOSTON SURGICAL SOCIETY

The monthly clinical meeting of the Boston Surgical Society will be held in co-operation with the Staff of the Paraplegia Service of Cushing Veterans Administration Hospital, Framingham, Massachusetts, on Friday, February 25. A symposium entitled "Some Aspects of Paraplegic Care" will be presented.

PROGRAM

Recreation Hall (9:30 a.m.)

Welcome and Introduction Drs. R. R. Gasser and H. S. Talbot

The Immediate Care of Patients Following Spinal-Cord Injury Dr. Donald Munro

Some General Metabolic and Hygienic Problems Dr. Joseph W. O'Neil

The Major Urologic Considerations Dr. Arthur Bassell
The Problem of Pain Drs. John H. Van Landingham and John T. O'Neil

Intermission — Visit to Ambulation Clinic (11:00 a.m.)

Ward (11:30 a.m.)

Demonstration of Tidal Drainage and Cystometry Dr. Melvin K. Lyons

The Surgical Treatment of Pressure Sores Dr. Robert T. Steinsieck

Discussion (12:00 m. to 12:30 p.m.)

For those who wish to remain, lunch will be served (60 cents) and there will be informal tours of the paraplegic wards and related departments after lunch. To facilitate adequate arrangements, guests who desire lunch should so notify Dr. H. S. Talbot, Cushing Veterans Administration Hospital, Framingham, Massachusetts, not later than Tuesday, February 22.

POSTGRADUATE INSTITUTE OF PHILADELPHIA COUNTY MEDICAL SOCIETY

The Philadelphia County Medical Society will hold its Thirteenth Annual Postgraduate Institute at the Bellevue-Stratford Hotel, Philadelphia, from April 5-8. The program has again been arranged on the basis of symposia, and the following subjects will be covered: diseases of the circulatory system, common conditions in the oral cavity, diabetes, anterior poliomyelitis, blood dyscrasias, diseases of the kidney, miscellaneous problems, pain, industrial medical and surgical problems, common obstetric problems, problems of infancy and childhood, eye, ear, nose and throat, gastrointestinal problems and vaginal discharge (causes and treatment).

There will be the usual number of high-grade technical exhibits.

The admission fee for the entire institute is \$5.00. Programs will be available very shortly.

For further details application should be made to Gilson Colby Engel, M.D., Director, 301 South 21st Street, Philadelphia 3, Pennsylvania.

AMERICAN BOARD OF OPHTHALMOLOGY

The American Board of Ophthalmology does not evaluate, approve or disapprove any ophthalmic residency toward fulfilling the requirements for candidates for board examination. Any candidate who qualifies for the board examination and completes the prerequisites as outlined in the booklet of information will be accepted. A copy of this booklet can be obtained from the secretary of the American Board of Ophthalmology, 56 Ivie Road, Cape Cottage, Maine.

AMERICAN ACADEMY OF GENERAL PRACTICE

Application blanks for membership in the American Academy of General Practice may be obtained from the secretary of the Massachusetts chapter, Dr. James G. Simmons, of Fitchburg.

INTERNATIONAL AND FOURTH AMERICAN CONGRESS ON OBSTETRICS AND GYNECOLOGY

The meeting of the International and Fourth American Congress on Obstetrics and Gynecology will be held at the Hotel Statler (formerly, Hotel Pennsylvania), New York City, on May 14 to 19, 1950, under the sponsorship of the American Committee on Maternal Welfare.

The preliminary program for the scientific sessions will include morning meetings, Monday through Friday, May 15 to 19, of general sessions each devoted to one of the following five topics: physiology of human reproduction, pathology of human reproduction, social and economic problems, neoplastic diseases of the female reproductive system, and obstetric and gynecologic procedures. The afternoons will be given over to meetings of various groups represented at the Congress, including nurses, nurse midwives, hospital administrators, educators, practicing physicians, investigators in special fields and public-health doctors and nurses.

Applications for space in the scientific exhibit or for time on the motion-picture program should be submitted to the chairmen in charge of these activities on official application blanks obtainable from the business office of the International Congress at 24 West Ohio Street, Chicago 10, Illinois.

All inquiries pertaining to the meeting should be addressed to the chairman of the International and Fourth American Congress on Obstetrics and Gynecology, Dr. Fred L. Adair, at 24 West Ohio Street, Chicago 10, Illinois. Mr. Karl S. Richardson is business manager.

BOSTON

THE disease generally known as "primary atypical pneumonia" or "viral pneumonia" is now well established as a clinical entity. The fully developed case can usually be recognized by the nature and course of the symptoms, the character of the physical and roentgenographic findings in the lungs, the absence of sustained leukocytosis and the failure to find significant pathogenic bacteria in the blood, sputum or lungs or to obtain clinical cures with the available antibacterial agents. Confirmation of the diagnosis is obtained in a large proportion of cases by the demonstration of cold agglutinins in the patients' blood late in the acute disease or during convalescence.

The ambiguous status of the etiology of this disease is still well characterized by the designation recommended early in the war by the Army Epidemiological Board, namely, "primary atypical pneumonia, etiology unknown."¹ The viral nature of the etiologic agent is strongly suggested by the transmissibility of the disease to normal human subjects by means of bacteriologically sterile filtrates of sputum from active cases.² The only viral agent transmissible to laboratory animals that seems to fulfill the criteria for the etiology of this disease is that of Eaton,³ but his findings still await confirmation by other workers. Furthermore, the finding of certain strains of nonhemolytic streptococci in cultures of lungs and sputum of a number of cases of this disease and the demonstration of agglutinins for these streptococci during convalescence in a significant proportion of cases suggest a possible synergism of such bacteria and some unknown virus in the causation of the disease.⁴ There is also the possibility and even likelihood that several distinct nonbacterial agents, as yet undiscovered, produce the same clinical picture.

Irrespective of its etiology, it is generally agreed that there is no definitive therapy for this disease entity. All workers agree that the sulfonamides and penicillin are entirely ineffective in primary atypical pneumonia except possibly so far as they may influence bacterial complications, and even the evidence for the occurrence of such complications in any appreciable number of cases is quite meager. Although streptomycin is also usually included among the antibacterial agents that are said to be without effect on this disease, published reports of its use under controlled conditions in any significant number of cases could not be found.⁵ Convalescent serum does not offer a practical therapeutic approach, and even the favorable reports of its use are not entirely convincing.

The discovery of aureomycin,⁶ an antibiotic agent that is highly effective against infections with all the known rickettsias and the viruses of the psittacosis-lymphogranuloma-venereum group in animals and in such human cases as there has been opportunity to observe to date, is of particular interest in relation to primary atypical pneumonia. The manifestations of human infections with psittacosis and Q fever are virtually indistinguishable from those of primary atypical pneumonia in which the etiologic role of these or any other known agents can be ruled out. Moreover, other rickettsias, such as those causing epidemic typhus, which are not usually thought of as causes of pneumonia, may produce symptoms and pulmonary lesions that are indistinguishable from those of primary atypical pneumonia except by specific serologic tests or by isolation of the rickettsia. It seems quite possible, therefore, that some as yet undiscovered agent or agents of one of these groups cause some of the cases now classified as primary atypical pneumonia, etiology unknown.

At any rate, it seemed quite reasonable to attempt empirically to determine whether aureomycin would favorably influence the course of this disease. Furthermore, the wide "valence" of the activity

⁵In a cursory review of the literature dealing with either streptomycin or primary atypical pneumonia, direct reference was found to only 2 cases and in both of them the streptomycin had no effect on the course of the disease.

of aureomycin and its relatively low toxicity served to minimize the hazards of a clinical trial with this agent, since it has been found to be effective both in vitro and in vivo against a large variety of gram-positive and gram-negative bacteria, including those that are commonly found as causes of pneumonia.⁶ A preliminary clinical trial in a few cases of pneumococcal pneumonia yielded results comparable with those obtained in similar cases treated with sulfadiazine or penicillin.⁷

It is the purpose of this paper to present and discuss some observations made in the course of the clinical evaluation of the effects of aureomycin

consider for aureomycin treatment only cases of at least moderate severity in which the clinical and x-ray picture was clearly defined and the patient was acutely ill at the time. When the patient was first seen, the duration of symptoms of the disease was estimated as nearly as possible. This was not always a simple matter because of the occurrence of upper respiratory symptoms before or during the illness and the relation of these symptoms to the pulmonary infection could not be readily assessed. When there was any reason to suspect that the acute disease was receding, as evidenced by recent improvement in the general appearance of

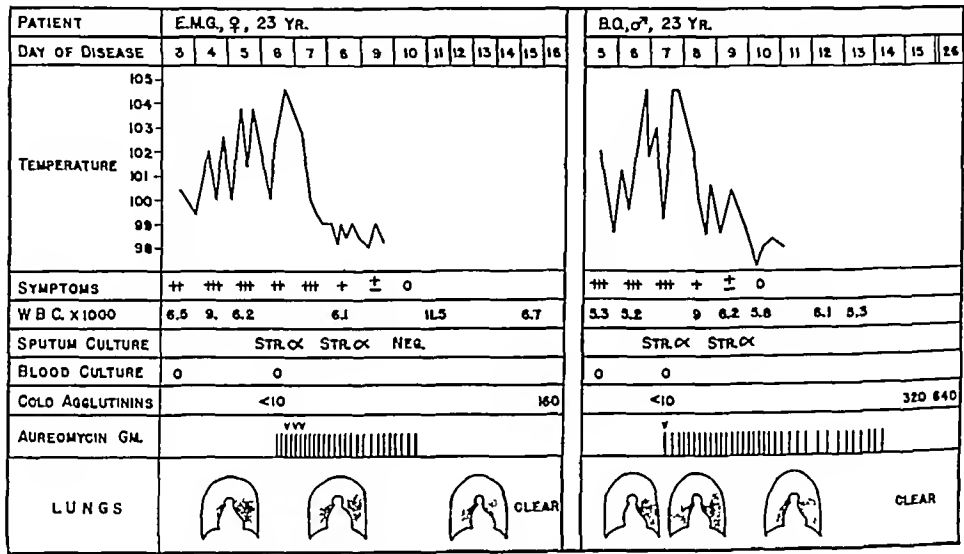

FIGURE 1 Primary Atypical Pneumonia Treated with Aureomycin by Mouth

in a few selected cases of primary atypical pneumonia. The cases are presented from the point of view of the critical interpretation of these observations rather than in any attempt to arrive at a definitive conclusion concerning the actual effectiveness of aureomycin in this disease. The latter must await experiences with a considerably larger number of cases.

MATERIALS AND METHODS

Selection of Cases

The patients included here were all young adults either from the various medical services of the Boston City Hospital or from other nearby hospitals where they were observed and the data obtained through the courtesy of their attending physicians.

On the assumption that the great majority of cases of primary atypical pneumonia are quite mild and offer considerable difficulty in interpretation of the effects of the trial agents, it was decided to

the patient or in the fever or symptoms, the patient was first observed for a few hours. The aureomycin was then given only if the temperature rose again and the symptoms returned to the previous severity or got worse, and the antibiotic was withheld if the improvement continued. If other drugs or antibiotics had been used, this delay afforded additional time for evaluation of their effects.

Laboratory Studies

The usual laboratory data, including blood and sputum cultures and white-cell counts, were obtained. In addition, blood was taken for estimation of the cold-agglutinin titers and for other serologic tests before treatment was started and again at suitable intervals.

Dosage

All the aureomycin was given by mouth in the form of capsules of the crystalline hydrochloride. The dosage used was 1 gm. every four to six hours until the temperature had become essentially nor-

mal for a few hours and every six to eight hours for an additional two or three days. The less frequent doses were usually employed in patients who exhibited nausea or vomiting. This dosage was chosen arbitrarily and no attempt has been made, as yet, to determine the optimum dose.

CLINICAL RESULTS

All the patients included in this study had the classic clinical and laboratory findings of primary atypical pneumonia. The onset was rather insidious, with chills or chilly sensations, and these were followed by increasing malaise, rather severe

tive, and cultures of the sputum yielded only the common mouth organisms, *Streptococcus viridans* usually predominating. Significantly high cold-agglutinin titers, usually 1:160 or higher, were attained in the serum at the proper time in every case.

The number of patients who have been treated with aureomycin to date is too small for any statistical evaluation. In every case, however, the temperature fell to and stayed at normal levels within twelve to thirty-six hours of the first dose, and this was accompanied by a loss in "toxicity" and improvement in the systemic and respiratory symp-

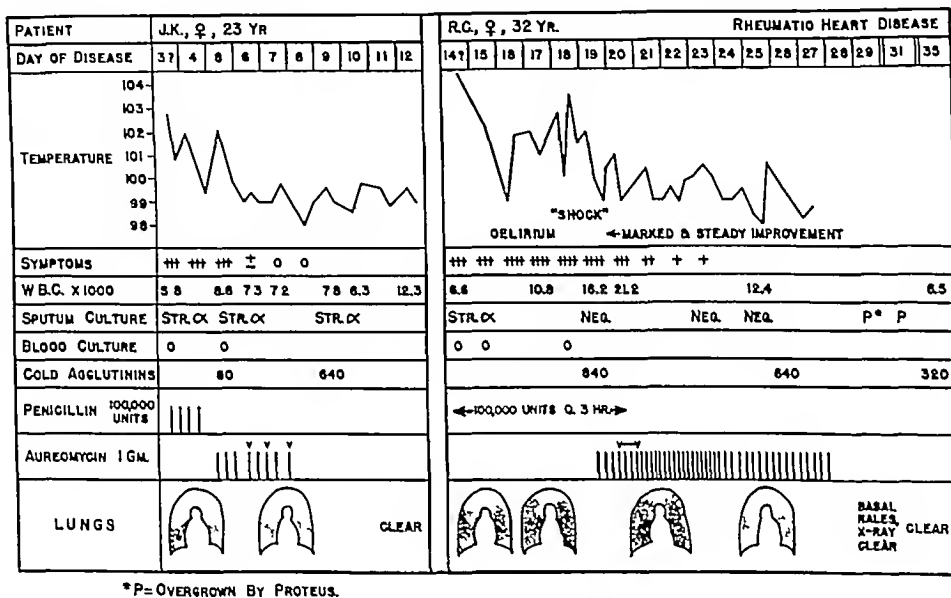

FIGURE 2 Primary Atypical Pneumonia Treated with Aureomycin by Mouth

generalized headache, prostration, irritating cough, which was either dry or productive of scanty yellowish mucoid sputum, and soreness of the anterior portion of the chest and costal margins but no true pleuritic pain. In most cases there was only slight if any dyspnea or cyanosis when the patient was at rest, but these symptoms were present or became accentuated on very slight exertion. There was only slight or moderate dullness to percussion over some parts of the lungs, with only minor or transient changes in the breath sounds or the whispered and spoken voice, but in every case there were large areas of the chest over which showers of medium crepitant rales were heard. Roentgenograms showed the characteristic soft nodular shadows scattered through extensive areas of the lungs, and some also showed patchy areas of partial atelectasis. The white-cell counts were essentially normal except for slight and transient leukocytosis in some cases. Blood cultures were all nega-

toms, without further demonstrable extension of the pulmonary lesions and with evidence of progressive clearing of the lungs thereafter. Nausea—with or without vomiting, which seemed to occur quite frequently with some of the lots of aureomycin given in large doses—seemed to obscure the early symptomatic improvement in some of the patients, but this usually subsided as recovery set in even though the administration of the antibiotic was continued. The findings are best illustrated by a brief résumé of the first 4 cases in which the aureomycin was used. Some of the more relevant data in these cases are shown in Figures 1 and 2.

E M G (Fig 1) was first considered for aureomycin therapy on the 6th day of illness. There had been downward swings in the temperature on that day and on previous days, but each of these had occurred in response to the administration of aspirin and each was followed by rises to or above the previous peaks with aggravation of the headache and systemic symptoms. Aureomycin was started during an upward swing in fever and no further aspirin was given. The temperature reached normal and

of aureomycin and its relatively low toxicity served to minimize the hazards of a clinical trial with this agent, since it has been found to be effective both in vitro and in vivo against a large variety of gram-positive and gram-negative bacteria, including those that are commonly found as causes of pneumonia.⁶ A preliminary clinical trial in a few cases of pneumococcal pneumonia yielded results comparable with those obtained in similar cases treated with sulfadiazine or penicillin.⁷

MATERIALS AND METHODS

Selection of Cases

The patients included here were all young adults either from the various medical services of the Boston City Hospital or from other nearby hospitals where they were observed and the data obtained through the courtesy of their attending physicians.

On the assumption that the great majority of cases of primary atypical pneumonia are quite mild and offer considerable difficulty in interpretation of the effects of the trial agents, it was decided to

the patient or in the fever or symptoms, the patient was first observed for a few hours. The aureomycin was then given only if the temperature rose again and the symptoms returned to the previous severity or got worse, and the antibiotic was withheld if the improvement continued. If other drugs or antibiotics had been used, this delay afforded additional time for evaluation of their effects.

Laboratory Studies

The usual laboratory data, including blood and sputum cultures and white-cell counts, were obtained. In addition, blood was taken for estimation of the cold-agglutinin titers and for other serologic tests before treatment was started and again at suitable intervals.

Dosage

All the aureomycin was given by mouth in the form of capsules of the crystalline hydrochloride. The dosage used was 1 gm. every four to six hours until the temperature had become essentially nor-

then started on injections of 0.5 gm of streptomycin every 6 hours and when first seen she had already received four such injections. During the 4 hours immediately preceding this visit the temperature had dropped appreciably, she was free of headache, and the malaise had eased considerably for the first time without antipyretics or analgesics. The streptomycin was continued for another 36 hours, during which she became entirely afebrile and symptom free and the lungs began to clear rapidly. Further injections of aqueous penicillin were given by a physician "to prevent secondary bacterial infection" while she remained in the hospital.

S S had a more severe illness and more extensive pulmonary involvement when he was first seen by one of us at a hospital in another city. It was the 9th day of illness, and he had received moderately large doses of penicillin during the previous week and these doses had been increased on that day. In addition, at the end of the 7th day, when the temperature reached 104.3°F, the pulmonary lesion had spread and the patient appeared to be getting much

mild or seemed to be improving either without specific therapy or while only penicillin was being given. The course of events in a patient in whom penicillin therapy was continued without the addition of either streptomycin or aureomycin may be mentioned. This patient was seen with a view to aureomycin therapy during the low points of his fever on the fourth and fifth days of his illness. On each occasion antipyretics had not been given, and it was believed that the patient might be improving spontaneously so that if aureomycin were started at that time it would not be possible to assess its effects. The course of this patient during the next ten days was characterized by a low-grade fever, severe cough, moderate malaise and head-

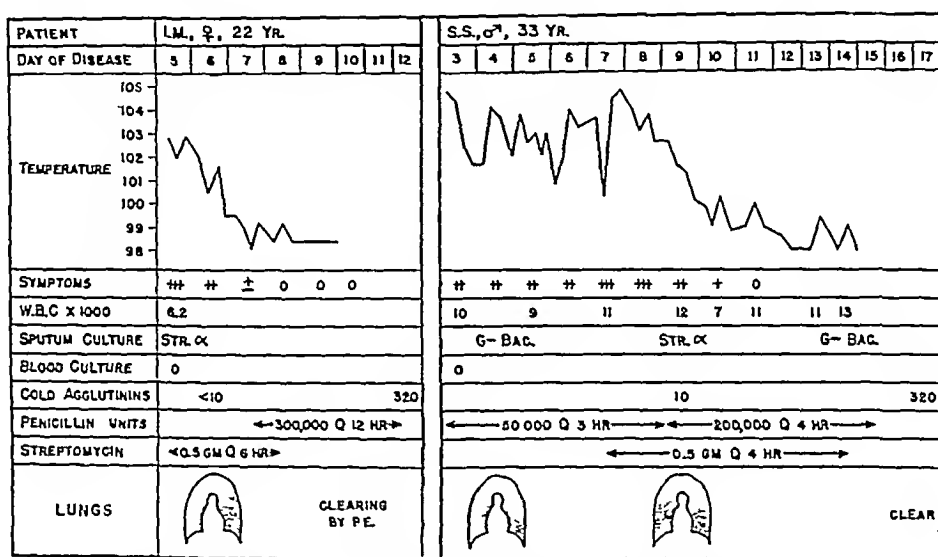

FIGURE 3 Primary Atypical Pneumonia Treated with Penicillin and Streptomycin

worse, he was started on injections of streptomycin (0.5 gm every 4 hours). He had already received a total of 5 gm at the time when he was seen. It was then apparent from his temperature chart that his fever was receding gradually but steadily, and, although he was still moderately ill, slightly cyanotic and sweating profusely, he readily admitted that he had been improving steadily in every respect during the preceding day. Aureomycin was, therefore, withheld, and, under further observation, he continued to improve steadily, and his lungs began to show signs of clearing during the next 2 or 3 days.

The acute febrile illness terminated on the seventh day in I M and on the tenth or eleventh day in S S. In both patients, as in the 2 cases shown in Figure 1, there were no cold agglutinins in the serum when aureomycin therapy was first considered, and high titers appeared in later specimens in each case. The effect of streptomycin in these 2 patients obviously cannot be assessed with certainty, but the favorable course following its use at least suggests that this antibiotic had a beneficial effect on the course of their disease.

In an occasional patient the symptoms during the first day or two of observation were relatively

ache, with some extension of the pulmonary lesion by physical and x-ray examination. Cold agglutinins, which were absent at first, were present in low titer on the eleventh day and in a much higher titer a week later. This case illustrates the fact that it has not been possible, on the basis of observations made during the first few days of the acute illness, to predict the subsequent course of the disease.

The question then is, How may one arrive at a reasonable estimate of the true value of these apparently effective agents in a disease with so variable a course as primary atypical pneumonia in which the early stages are so ill defined? It seems obvious from the cases presented that if treatment with the trial agents is withheld until the patients show progressively increasing severity of the symptoms or extension of the pulmonary lesions, the use of these agents will be confined essentially to a stage of the disease when the illness may be expected to terminate spontaneously in increasing proportions of cases.

remained so within 18 hours. Symptomatically, the patient complained of marked nausea, and she vomited three of the doses during the first 24 hours. She improved steadily thereafter, and the nausea and vomiting subsided in spite of the fact that aureomycin was continued for 3 more days. The lungs began to clear promptly and were entirely clear by physical and x-ray examination a week after the antibiotic had been started.

The course of events in B O (Fig 1) was quite similar. Some of the downward swings in temperature followed the taking of aspirin, and others followed alcohol sponge baths. Aureomycin was first given on the 7th day of illness when the temperature was again rising and the lesion in the lung was apparently spreading. This patient vomited once after the first dose, but the temperature dropped precipitately and he was markedly improved within 24 hours of the first dose. The signs in the lungs began to clear in the next 2 days and were entirely clear within 1 week.

Neither of these patients received any other antibiotics or any sulfonamide therapy. Both were essentially well by the eighth or ninth day of the disease. Inasmuch as spontaneous improvement at that time occurs quite frequently in this disease, it cannot be stated with any assurance that the termination of the acute illness in these patients was caused by the aureomycin in spite of the fact that the course of the symptoms in relation to the administration of the antibiotic is strongly suggestive. The absence of cold agglutinins at the time treatment was started and their presence in high titer later may be taken as additional evidence favoring such an interpretation.

In J K (Fig 2) it was difficult to determine the exact duration of the pneumonia. This patient had had an upper respiratory infection with coryza, headache, mild fever and slight nonproductive cough for 2 weeks before she came to the hospital. During this time she had slight chilly sensations and sweats, but she had been taking aspirin frequently and was able to stay at her work until 2 days prior to admission. At that time she had a shaking chill, followed by a severe headache and exacerbation of the previous symptoms with more frequent and severe paroxysmal cough productive of greenish and occasionally blood-tinged sputum. She was given sulfadiazine by a physician, but the symptoms grew steadily worse. She became nauseated and vomited. She was then referred to the hospital, where she remained acutely ill for 2 more days under penicillin therapy. On the 3rd hospital day, when the temperature was again rising, she was started on aureomycin. The fever and symptoms began to improve promptly and she was afebrile and her systemic symptoms had largely subsided in less than 24 hours after the first dose. This patient had some nausea, and she vomited three of the doses on the 2nd and 3rd days and the drug was then discontinued. The lungs began to clear at this time and were entirely clear by physical and x-ray examination 1 week later.

In this case, again, the prompt improvement that followed the administration of aureomycin strongly suggested a causal relation. The finding of an elevated cold-agglutinin titer when this treatment was started, even though the titer later rose significantly, suggests that the disease was of two weeks' rather than five days' duration at that time. The possibility of a normal termination of the acute illness coincidental with the start of aureomycin therapy must, therefore, be considered.

The course of events in R C (Fig 2) again strongly suggests a remarkable and prompt effect from aureomycin, but a critical evaluation of all the data likewise raises con-

siderable doubt. This patient, who was known to have had rheumatic heart disease for at least 7 years, had been ill at home for 2 weeks with chills and fever and a hacking cough productive of yellow and occasionally "frothy, pink" sputum. During this time she was treated with sulfadiazine, but she became much worse 2 or 3 days prior to entry, when she was thought to have cardiac failure and so was sent to the hospital. The symptoms and signs in the lungs at the time of admission were consistent with either diffuse pulmonary congestion or extensive pneumonia, or both. She failed to respond to cardiac therapy and to large doses of penicillin and became confused and disoriented, dyspneic and cyanotic and finally appeared to be in "shock." On the 6th hospital day while in this condition she was started on aureomycin. All the symptoms showed perceptible improvement 18 hours after this therapy had been started and within the next 2 days she was remarkably improved so that her appetite returned and she breathed much more comfortably. The lungs began to clear rapidly, and she was free of all symptoms by the end of the 1st week. Except for a few basal rales the lungs were entirely clear after 2 weeks.

In this patient a high titer of cold agglutinins at the time aureomycin was started was consistent with the long duration of the illness at that time. Although this suggests that the recovery was spontaneous, all the physicians who observed the patient were convinced that she was failing rapidly, that her chances of recovery were very slight indeed when treatment with aureomycin was started and that the administration of this agent was in large measure responsible for the beginning of her recovery.

In the other patients with primary atypical pneumonia who were treated with aureomycin the course before and after this treatment was essentially similar to that noted in the cases cited above. There was also similar difficulty in assessing the role of the aureomycin in each patient, in spite of the fact that they were all acutely ill and not showing evidence of improvement when administration of this antibiotic was started.

During the period when these cases were being observed, however, a considerably larger number of patients with similar clinical findings were seen but in them aureomycin treatment was withheld. These patients differed from the first group only in that, either subjectively or objectively, they seemed to be improving sufficiently to suggest that they were approaching the termination of their acute illness although they were still febrile and moderately ill when they were first considered for aureomycin therapy. In almost every case the subsequent clinical course was in every way similar to that of the 3 cases cited above, in spite of the fact that aureomycin was not used. Two of these cases are of particular interest because the findings suggest that clinical improvement occurred in response to the administration of streptomycin. Some of the relevant findings in these 2 cases are shown in Figure 3.

I M was first seen with a view to aureomycin therapy on the day after admission to another hospital. It was the 6th day of illness, and the symptoms were becoming progressively worse. She had received injections of 300,000 units of procaine penicillin in oil on each of the 2 days preceding admission, and this had been discontinued. She was

OVARIAN NEOPLASMS IN A HERMAPHRODITE*

THOMAS F. CORRIDEN, M.D.†

NORTHAMPTON, MASSACHUSETTS

HERMAPHRODITISM in itself is a rare anomaly. The additional occurrence of bilateral gonadal neoplasms is exceedingly uncommon. The present paper reports the case of a "male" hermaphrodite with a pseudomucinous cystadenoma of the right ovary and a dysgerminoma (seminoma) of the opposite gonad.

GENERAL CONSIDERATIONS

Hermaphroditism is the term used to designate the congenital possession by one person of both male and female sex organs. Two forms exist, true hermaphroditism and pseudohermaphroditism. Diagnosis of the former requires the presence of both ovary and testis either as separate organs or combined to form unilateral or bilateral ovotestes. In pseudohermaphroditism, on the other hand, the gonads are either ovarian or testicular, and only the secondary sex organs are both male and female.

True hermaphroditism is quite rare, only 38 cases appearing in the literature.¹ Pseudohermaphroditism, in contrast, is stated to occur to some degree in 1 out of every 1000 females, it is considerably less frequent in males.¹

Tumors occurring in hermaphrodites may arise from ovarian or testicular tissue, in pure organs or in ovotestes, often the gonad is destroyed by the neoplastic process so that the site of origin is impossible to determine.

No neoplasm is found in constant association with hermaphroditism. The most commonly reported one is the dysgerminoma,² a highly radiosensitive malignant tumor composed of large, clear epithelial cells growing in diffuse sheets or nests isolated by a stroma rich in lymphocytes. According to Meyer³ the dysgerminoma is a tumor of the neuter germ cell of the embryo, it arises in ovarian or testicular tissue, in the latter site it is better known by the names, seminoma⁴ and embryonal carcinoma.⁵ Meyer³ collected 27 cases of dysgerminoma occurring in hermaphrodites. Five were bilateral. Two of the 27 patients had an ovotestis on the side opposite the tumor.

In addition to hermaphrodites the dysgerminoma tends to occur in persons with less striking sexual abnormalities, including male cryptorchidism and female hypoplasia of the genital organs. The majority of dysgerminomas, however, arise in apparently normal men and women.⁶

Beyond the observation that dysgerminomas are encountered with unusual frequency in persons who

approach neutrality in sex, there is no apparent causal relation between dysgerminoma and hermaphroditism, for the latter is a congenital malformation that remains despite removal of the tumor.

A second tumor that has been reported with some frequency in hermaphrodites is the so-called tubular adenoma of the testis.⁷ This occurs as single or multiple small nodules in the cryptorchid testicles of both normal and hermaphroditic patients. It appears in most if not all cases to be a nodular hyperplasia in an atrophic, cirrhotic organ rather than a true neoplasm, it has no clinical significance.

One of the most controversial aspects of hermaphroditism is the proper classification of patients with arrhenoblastomas — that is, ovarian neoplasms that resemble testicular tissue and often cause masculinization. These tumors range from tubular adenomas, which may bear a striking resemblance to the so-called adenomas of the cryptorchid testicle, to highly undifferentiated sarcomatoid forms. According to Pick⁸ the tubular adenoma arises in the testicular portion of an ovotestis, hence, a person with such a tumor is a hermaphrodite by definition. Meyer,³ on the other hand, believed that the assumption of the existence of an ovotestis is not necessary since the embryonic rests of testicular tissue present in the normal ovary adequately account for the occasional occurrence of masculine tumors. In support of this is the fact that convincing evidence of congenital hermaphroditism is quite rare in patients with tubular adenomas.⁹

Gonadal neoplasms other than dysgerminoma and testicular adenoma have been reported in small numbers of hermaphrodites.^{9, 10} No case of pseudomucinous cystadenoma of the ovary was encountered in an extensive, albeit incomplete, review of the literature.

CASE REPORT

A 38-year-old patient, stated to be a man, who was married but had no children, was admitted to the hospital complaining of pain and discomfort in the abdomen.

The father was living, aged 77. The mother had died in 1927 from leukemia. One sister was living and well; she was married and had 3 children.

At the age of 1½ the patient was in the hospital for some sort of operation on the penis, and at the age of 3 he was confined to the hospital because of trouble with urination. From that time until he was 35 he had absolutely no trouble.

For a year prior to admission to the hospital the patient had been having episodes of pain and discomfort in the abdomen associated with nausea and vomiting. He had been married for 11 years and as far as could be ascertained he had sexual relations with his wife. Four weeks before admission the patient had suffered low-back pain and diarrhea. There were no bloody stools. The pain gradually migrated laterally to the mid-lower abdomen.

The temperature was 99.5°F by rectum. The blood pressure was 130/70, the pulse 85 and the respirations 20.

*Presented at the annual meeting of the New England Surgical Society, New Haven, Connecticut, October 1, 1948.

†Chief Surgical Service, Cooley Dickinson Hospital, consultant, Northampton State Hospital.

Were all cases to be treated as soon as the diagnosis of primary atypical pneumonia is made or suspected on clinical grounds, the great majority of the patients treated might turn out to have either a disease that is ill defined (undifferentiated acute respiratory disease⁸) or at most a rather mild case of primary atypical pneumonia in which the effects of the agents would be difficult to assess. Proof of the effectiveness of these agents in the cases that proved to be primary atypical pneumonia would, in any event, have to depend on the demonstration of a constant beneficial effect in consecutive cases and in direct relation to the initiation of the treatment. In addition, adequate causes, extraneous to the primary pulmonary infection, would have to be established to account for the failures.

On the other hand, should any appreciable number of such patients show a progression of symptoms and pulmonary lesions under adequate doses of one of these agents, it would be possible to state with some assurance that that agent was not specifically effective in this disease. On the basis of this argument, the few cases of primary atypical pneumonia in which streptomycin is said to have had no effect on the course of the disease are more significant than the 2 cases in which a possible beneficial effect was noted, provided, of course, that the same criteria were used for diagnosis.

The patients with whom we are concerned in the present evaluation were acutely ill and febrile when aureomycin was started, and each had a history and physical examination. X-ray and laboratory findings were characteristic of primary atypical pneumonia. The first 20 consecutive patients who satisfied these criteria and, in addition, developed significant titers of cold agglutinins in their blood at the appropriate time were all markedly improved clinically and were afebrile within twelve to forty-eight hours (the great majority within twenty-four hours) after the first dose of aureomycin was given. The pulmonary lesions then cleared rapidly in every case. On the basis of these consecutive favorable responses, therefore, aureomycin may be said to be highly effective in the treatment of cases of primary atypical pneumonia of the variety that is associated with the development of cold agglutinins. Further details of these cases and the findings in cases of other types of pneumonia that have been treated with aureomycin will be given in a later report.

While this study was in progress, similar studies on the effects of aureomycin in primary atypical

pneumonia were being carried out by several other groups of workers. Reports from two of these groups, one from New York⁹ and the other from Baltimore,¹⁰ have already appeared. In each instance favorable responses similar to those reported here were noted in consecutive cases of this disease, and in the majority of the cases cold agglutinins were demonstrated at the appropriate time. Both groups of workers are convinced that aureomycin has a definitely favorable effect on this disease.

SUMMARY

A small group of patients with the characteristic clinical, x-ray and laboratory findings of primary atypical pneumonia were treated with aureomycin by mouth. They were all moderately or severely ill when this treatment was started, and their fever and symptoms began to improve promptly and subsided in all cases within twelve to forty-eight hours. Cold agglutinins appeared in high titer late in the acute illness or during convalescence in the serum of all of these patients. The findings in these cases suggest that aureomycin had a favorable effect on the course of the disease.

Two cases are presented in which a somewhat similar course of events followed the administration of streptomycin.

The problem of the evaluation of curative agents in primary atypical pneumonia is discussed in relation to the findings in these cases.

We are indebted to Mildred W. Barnes for carrying out the cold-agglutination tests, and to Clare Wilcox for bacteriologic studies of the sputums.

RIGHT- OR LEFT-HANDEDNESS*

A Practical Problem

RICHARD S. EUSTIS, M.D.†

CHESHAM, NEW HAMPSHIRE

A PHYSICIAN who is asked if it is safe and wise to train an apparently left-handed child to use pencil and pen with his right hand can find good authority in the literature for almost any answer he may choose to give. The more he studies the subject, the more confusing it becomes. The theories propounded are various and conflicting.

If he then tries to form his own opinion by testing and observing his patients he soon finds that his decision whether a given child is right-handed, left-handed or ambidextrous often depends on the number and type of tests used. If his bias is toward a comparatively large number of ambidextrous subjects, all he need do is administer a large battery of laterality tests that include the relatively unskilled activities. On the other hand, a smaller battery testing chiefly the skilled activities will give less evidence of ambidexterity and more of definite right-handedness or left-handedness. There are many exceptions, but by and large the more tests that are given and the more the untrained activities are included the greater the amount of mixed or confused dominance that will be found.

The problem of handedness is actually a double one, although the duality is ignored by many. The first question is why man alone among primates has developed a preferred hand, and the second is why in approximately 95 per cent of adult, civilized, tool-using peoples the preferred hand is the right.

GENERAL CONSIDERATIONS

Although man from most anatomic points of view is a bilaterally symmetrical animal, he is in reality decidedly asymmetrical in function. Attempts have been made to demonstrate this asymmetry in some of the lower animals, such as the rat, horse, dog, monkey and ape. It cannot be denied that some of these at times show a preference for one side over the other, but this vague, indefinite preference is far from the skilled, unilateral handed-

ness shown by the great majority of human adults. Monkeys and apes have developed unilaterality a little farther than the others in that they manipulate an object with one hand while the other is used for support or for holding and steadying, but they seem to have no great preference regarding the hand that does the manipulating. The ability to develop a preferred and hence more skillful hand is a characteristically human trait, which apparently has arisen as an inevitable result of man's one-handed use of tools and weapons. It seems clear that the acquisition of skill in one hand is a gradual process largely dependent upon training through habitual use.

Man's unilateral handedness, however, is fluid, not fixed. What one hand can do the other can also do, although until practiced it is slow, clumsy and awkward. This bimanual ability is exemplified by the skill of the pianist and typist with the ordinarily nonpreferred hand. The fluidity is particularly marked in childhood when the preferred hand is still far from skillful and the nonpreferred hand can do almost as well as the other.

HANDEDNESS IN INFANCY

Handedness in infancy means only the somewhat more frequent use of a particular hand for reaching, touching and eventually grasping objects. This sort of activity is very different from the handedness of an adult, whose habitual use of one hand has greatly increased its skill. In the infant and young child the more frequently used hand shifts from side to side at fairly definite intervals, with periods when both hands are used either together or with no choice between them.¹⁻⁵ The studies of Conel⁶ suggest that this alternation in use depends upon changes and new connections in the constantly growing association tracts. Whatever the cause may be, the practical result is that both hands receive some training, so that the final outcome is, 'not a good hand and a poor one, but a good hand and a better one.'"

*From the Language Clinic, Massachusetts General Hospital.

†Member, Board of Consultants, Massachusetts General Hospital.

Physical examination revealed a rather short, stocky, slightly obese man weighing about 140 pounds. The patient had a normal beard and a normal distribution of hair over the entire chest. Examination of the abdomen revealed a slight bulge in the right lower quadrant. Palpation disclosed a smooth, round, nontender tumor. The left side of the lower abdomen appeared normal. Examination of the genitalia showed a normal growth of pubic hair, with complete absence of the scrotum. There was a typical hypospadiac penis, which was small (approximately 4 cm long). The prepuce was not covered with skin. Approximately 4 cm back from the head of the prepuce there was an opening through which he urinated. There was no opening in the head of the penis. Rectal examination was entirely negative.

A barium enema showed the colon to fill and evacuate well, without evidence of intrinsic disease. A normal-appearing appendix was visualized. There was a discretely outlined oval mass, 11 by 15 cm, displacing the cecum upward. The mass was situated in the right lower hypogastrium and pelvis. The impression was that of a malignant tumor, as noted, originating in an undescended testis. Pyelography was recommended to rule out the lesser possibility of renal tumor.

Intravenous pyelography showed normally draining structures bilaterally. The only abnormality to be seen was a slight extrinsic pressure defect on the right ureter, displacing it medially.

The diagnosis was abdominal tumor, probably testicular in nature. Under continuous spinal anesthesia a long incision was made in the right lower quadrant. When the abdomen was opened a large, round, smooth, thin-walled tumor, apparently ovarian in origin, was found. The tumor, approximately 15 cm in width, was attached to a small, hard mass, which was posterior to the urinary bladder. Further observation disclosed a large, hard, irregular mass, measuring 8.5 by 7 by 3 cm, in the left pelvis, which was well encapsulated and firm to palpation. The incision was enlarged, and further examination revealed a small, hard, fairly well developed uterus, which ran off into a small tubular structure just beneath the bladder. At this time a sound was passed through the meatus and could be palpated in the urinary bladder. The small tubular structure evidently ended in the peritoneum of the pelvic wall. Both tumors with the tissue attached to them were removed and given to the pathologist. Nothing further was done. The abdomen was closed without incident.

Postoperatively the patient did extremely well except for the 2nd night after operation, when he began to complain of severe hot flashes. He was given stilbestrol, 0.1 mg nightly. After a few days the hot flashes diminished. He was discharged from the hospital 12 days after the operation and has since been on stilbestrol therapy.

The pathological report was as follows:

The gross specimen consists of a cyst (from the right pelvic mass) measuring 15 by 13 by 8.5 cm. It is translucent, and when the wall is incised, it is found to contain about 750 cc of a clear, serous fluid and the cyst is multiloculated. The inner lining of the cyst is smooth. One of the cysts is filled with a chocolate-colored material.

There is an irregular, lobulated mass (from the left side of the pelvis) measuring 8.5 by 7 by 3 cm. It appears well encapsulated and is fairly firm to palpation. On section it is almost solid and is yellow gray. The cut surface is glistening. Attached to one side of this tumor is a tubular structure, which grossly resembles a fallopian tube.

Two sections taken from the cyst of the right gonad show a multilocular, pseudomucinous cystadenoma. The cysts, which vary considerably in size, are surrounded by dense collagenous tissue that bears a striking resemblance to ovarian stroma. The cyst lining varies from a columnar mucus-secreting epithelium to an indifferent squamous one, in some areas the lining cells are piled up, however, there is no evidence of malignancy. Occasional cysts are filled with serous fluid. The stroma surrounding the cysts may be extremely cellular with crowded, plump fibroblasts or may show hyalinization. In the cellular areas cords of epithelioid cells become intimately mixed with the stromal elements. The former are polyhedral and are characterized by distinct cell borders, abundant pale cytoplasm denser centrally, and pale, round, central nuclei, their appearance is suggestive of theca interna cells. The tumor is encapsulated by a layer of dense collagenous tissue resembling

tunica albuginea. No testicular or specific ovarian elements (other than stroma) can be identified in the sections. External to the capsule of the tumor is a tubular structure that has the characteristics of the isthmus portion of a fallopian tube.

One section taken from the tumor of the left gonad shows a dysgerminoma characterized by interlacing cords and alveoli of uniform polyhedral cells separated by a collagenous stroma rich in lymphocytes. The cytoplasm of the tumor cells is clear and has a somewhat vacuolated appearance owing to post-mortem degeneration. The nuclei are round to oval, contain heavy granular chromatin and show slight to moderate variation in size and shape. There are occasional mitoses. Small numbers of epithelioid cells and multinucleated giant cells filled with fine fat droplets are present, especially at the periphery of the cords. The tumor is encapsulated by a layer of dense collagenous tissue resembling tunica albuginea. No testicular or ovarian tissue is identifiable.

A final section taken from the tubular structure attached to the left gonadal tumor shows epididymis and a large duct lined by alternating groups of tall and low cells, giving the lumen a festooned circumference, which suggests that the duct is a ductulus efferens of the testis despite its large size.

The diagnoses are dysgerminoma of the left ovary, pseudomucinous cystoma of the right ovary and rudimentary fallopian tube.

DISCUSSION

In summary, this patient had both male and female secondary sexual organs. Was "he" a true hermaphrodite or a female pseudohermaphrodite? There is considerable evidence that the right gonad was an ovary; it was occupied by a pseudomucinous cystadenoma in which the cysts were surrounded by typical ovarian stroma*, pseudomucinous cystadenomas do not, to my knowledge, arise in the male gonad, and there was clinical evidence of estrogen withdrawal postoperatively. It is entirely possible that the cords of epithelioid cells in the stroma were estrogen-producing theca interna cells or that the stroma itself was estrogenic.

The identity of the left gonad presents an insoluble problem, no traces of testicular or ovarian tissue were present in the section of tumor. The tumor itself was consistent with an origin in either testis or ovary. The degree of nuclear hyperchromatism of the neoplastic cells is, in my opinion, a more common feature of the ovarian rather than the testicular dysgerminoma, this evidence, however, is only suggestive. In conclusion, then, it is believed that there is somewhat more evidence that this patient possessed two ovaries, and hence was a female pseudohermaphrodite. This conclusion is given some statistical support by the great rarity of true hermaphroditism.

UNILATERAL HANDEDNESS

At the present time the adult civilized world is approximately 95 per cent right-handed. The origins of this preference for the right are lost in prehistoric antiquity, and no theory accounts satisfactorily for the observed fact. The various hypotheses, some of them almost ludicrous in their simplicity, that attempt to explain it have been well summarized by Wile⁸ and Blau.⁹ Their reports of the agreed facts on right-handedness and left-handedness may be summed up as follows:

Archeologists have demonstrated that the amount of left-handedness has diminished from the dim past to the present. Implements dating from the Stone Age are reported to show that about 50 per cent were chipped or flaked for left-handed use. Only about 25 per cent of the weapons and tools from the Bronze Age were so fashioned, and at present no more than about 5 per cent of civilized peoples are left-handed.

Anthropologists report that there is more left-handedness among contemporary primitive races than among cultured, tool-using men.

Finally, there is a steady diminution in the frequency of left-handedness from infant to adult. Roughly 20 per cent of kindergarten children, 10 per cent of school children, and only 5 per cent of adults are reported to be left-handed.

RIGHT-HANDEDNESS DUE TO ENVIRONMENTAL PRESSURE

This steady increase of right-handedness with proportionate decrease of left-handedness — from the Stone Age to the present, from living primitives to cultured peoples and from child to adult — is convincing evidence of the importance of environmental pressure in determining ultimate handedness. As stated above, however, no theory accounts satisfactorily for the fact that this pressure is always in favor of the right. Whatever the original reason, the child of the present day has to live in and conform to a right-handed world.

THEORETICAL CAUSES OF LEFT-HANDEDNESS

Environment alone, however, does not explain the whole picture because it does not account for the persisting existence of a small proportion of left-handed adults. Some believe, without completely convincing proof, that left-handedness is inherited according to the Mendelian law. Others argue that it is acquired as the result of one of the following causes: temporary disablement of the right hand during childhood before the pattern has been firmly set, imitation of left-handed siblings, parents or other adults, deliberate training of a child's left hand by adults who mistakenly believe that because he is using his left hand about as much as his right he is going to be left-handed and help him to become so, and accidental training of the left

hand by an adult who when facing a child becomes confused himself between left and right. To these Blau⁹ adds childhood negativism, — the urge to act contrary to precept and to the example of the majority, — which he believes is responsible for most left-handedness. His argument is interesting although not wholly convincing and leaves the reader with the impression that negativism may account for some but surely not all left-handedness.

CHARACTERISTICS OF LEFT-HANDEDNESS AND AMBIDEXTERITY

The presence of left-handed and ambidextrous persons in a predominantly right-handed world has puzzled the curious ever since the days of the invasion and settlement of Palestine by the ancient Hebrews.¹⁰ Although the problem of their persisting existence may seem purely scientific or theoretical, it has its practical aspects as well.

A tendency toward ambidexterity appears to be more important in this connection than left-handedness itself. The strongly right-handed or left-handed person is not particularly prone to "specific" language disturbances,* which occur more frequently among the partly ambidextrous, regardless of whether they use the right hand or the left for most activities. Unusual aptitude with the nonpreferred hand is more common among left-handed than among right-handed people, as is obvious when one considers that all mature sinistrals use the right for shaking hands, many for eating, and some even for writing. Partial ambidexterity, rather than left-handedness itself, thus seems to be the important factor associated with these language disabilities.

Ambidexterity implies a mixed or varying cortical dominance, the left cortex taking the lead in some activities and the right in others. The nerve cells that are active in controlling language are, with rare exceptions, in the left cortex in right-handed and the right cortex in left-handed persons. Unfortunately, the only practical way to locate the functioning language center in normal persons is by inference from the patients' handedness. When that is confused or uncertain one is left in doubt. Orton¹¹ and others argue that lack of clear cortical dominance is the cause of the specific language disabilities. Although absolute proof of this hypothesis is lacking, it seems very clear that there is some relation between a tendency toward ambidexterity and comparative weakness in the use of language.

Left-handedness and ambidexterity are also more common among children, the mentally retarded, criminals and geniuses. This does not mean that they are causes of these conditions. Children are still in the original state of using both hands fairly equally, the mentally retarded, in this as in most respects, are still children, some criminals fall into

*Motor speech delay, infantile speech stuttering and specific reading disability are regarded as specific language disabilities.

the same group, whereas others seem to exemplify Blau's theory of a negativistic attitude toward the world, and geniuses by and large are extremely individualistic and hence more likely than the average to resist successfully the external pressures toward right-handedness

THEORIES OF LEFT-HANDEDNESS AND AMBIDEXTERITY

Of the many theories propounded to account for the existence of left-handedness and ambidexterity in a right-handed world, none have been widely accepted. In general they repeat with variations the old and endless dispute between the champions of heredity and of environment. Simply stated, the unsolved question is whether right-handedness and left-handedness are inherited as such or are acquired after birth as a result of imitation, training, and social and cultural pressure. In such a complex human skill as unilateral handedness, it seems likely that both factors are usually involved.

FLUIDITY OF HANDEDNESS IN THE INFANT AND SMALL CHILD

Right-handedness and left-handedness in the usual sense of the terms are absent in infancy. A baby has no particular skill with either hand and, as Blau⁹ states, should be classed as ambilateral rather than ambidextrous. Giesecke¹ reports that from a few hours after birth one hand is more active than the other and that later this more active hand is the one chosen for reaching and grasping. Gesell² has shown that more frequent use of a particular hand for reaching and grasping does not begin until the infant is at least sixteen weeks old. Throughout infancy this more frequent use of one hand should not be taken to mean that it is the dominant or master hand in the adult sense, it indicates merely that it is the preferred hand for the time being.

The truly skilled and leading hand does not appear for several years. In fact, as Giesecke,¹ Gesell² and others^{3, 4} have demonstrated, the most used hand shifts from side to side at fairly regular intervals for a number of years. Gesell states that an infant passes through definite phases of being right-handed, left-handed and bilateral. He has reported a number of children who were apparently right-handed at two years and equally left-handed at three years, before becoming finally and permanently right-handed at five years. Evidently it is not until habitual use of one hand over a long period has given that hand definitely superior skill that it is fair to describe its possessor as a right-handed or left-handed person.

Unless this normal variation of handedness in infancy and early childhood is kept constantly in mind, laterality tests of young children may be extremely misleading. Certainly no definite or final

conclusion about a person's ultimate handedness should ever be drawn from them.

INHERITANCE AS A CAUSE OF HANDEDNESS

The influence of environment on handedness has been shown. It seems very certain, however, that this is not the only factor concerned. Some cases of left-handedness and ambidexterity appearing in the same family over several generations may undoubtedly be ascribed to environment. In many others, however, the left-handed relatives were so widely separated in time or space that imitation could not have been responsible for their occurrence. One is therefore forced to admit that inheritance may also play its part in determining the final result.

Until fairly recently those who believed in the inheritance theory were forced to assume something in the genes that led to the eventual dominance of the left or right cerebral cortex and so to right-handedness or left-handedness. Their opponents meanwhile insisted that it was the more frequent use of the preferred hand that established dominance in the appropriate cortex.

A clue to how heredity may affect handedness has been suggested by Gesell.² He has traced back into fetal life a basic trend toward the final adult handedness by demonstrating a relation between the preferred tonic-neck-reflex position of the premature infant and his ultimate handedness. Since the tonic neck reflex develops as early as the twenty-eighth week after conception,¹² it seems impossible that environmental pressure after birth can do more than modify a fundamental tendency.

TONIC NECK REFLEX OF THE HUMAN INFANT

When a normal newborn infant turns his head to one side, the arm and leg on that side automatically straighten and extend themselves, the opposite arm bends toward the head, and the opposite leg flexes at the hip and knee. Equally automatically, this position reverses itself when the infant turns his head the other way. This obligatory response to the turning of the head is known as the tonic neck reflex.

It is present in typical form in all normal newborn babies, fading gradually and becoming replaced by symmetrical arm and leg movements by the time the infant is twenty weeks old. Its presence at an older age indicates serious disease of the brain.¹³

NEUROMUSCULAR DEVELOPMENT IN THE SALAMANDER EMBRYO

An example taken from a lower form of life is illuminating. Coghill¹⁴ succeeded in correlating the behavior of the amblystoma embryo at different stages of development with the growth of its nervous system. His account is fascinating and too little known among physicians.

At an early stage the embryo lies motionless and does not respond to stimulation. A little later it spontaneously "bends itself into a tight coil . . . [which] may be reversed instantly into a coil in the opposite direction." The flexing motion begins at the head and progresses caudad.

The next stage is the appearance of a second flexion of the head in the opposite direction before the first has reached the tail. These flexions, when better co-ordinated and more rapid, result in forward motion of the embryo, as in swimming. When the forelimbs are sufficiently developed, the one on the concave side is adducted, and the one on the convex side is abducted during flexion of the neck and trunk. These movements are the beginnings of forward motion of the body on land, as in walking.

Coghill demonstrated conclusively that the co-ordination of these flexions into swimming movements depends upon the growth of connecting cells in the floor of the medulla and in the upper part of the cord. "The growth of terminals of nerve cells over a distance of less than 1/100 of a mm transforms (the animal) from (one) that must lie helpless where chance has placed it into one that can explore its environment."

RESEMBLANCE BETWEEN SALAMANDER AND INFANT

There is a striking similarity between Coghill's drawings of *amblystoma* illustrating the beginning of walking and Gesell's photographs of infants in the tonic-neck-reflex position. The resemblance is so marked that it seems extremely likely that they represent approximately equivalent stages of development of the nervous systems of the two species.

RELATION OF THE TONIC NECK REFLEX TO HANDEDNESS

Gesell² reports that the great majority of infants when in the tonic-neck-reflex position spend more time with the head turned to the right than to the left. He followed 10 infants with predominantly right tonic neck reflexes for ten years and found that they all became right-handed children. He followed 9 with predominantly left tonic neck reflexes for the same period and found that 4 became left-handed and 5 right-handed. He is careful to draw no conclusions but merely comments that, although the tonic neck reflex is usually indicative of later handedness, there are interesting and significant exceptions.

He states that the strength and persistence with which the tonic-neck-reflex position is held varies greatly in different infants. It would be interesting to know if the 5 infants with left tonic neck reflexes who grew up to be right-handed were relatively weak in their tonic neck reflexes. Whether they were or not, and it seems likely that they were, it appears very probable that the 5 who changed from a predominantly left tonic neck re-

flex in early infancy to right-handedness in later childhood did so in response to environmental pressure. It is not wholly clear why the remaining four did not change also. It may be that their preference was unusually strong, or it may be that they were influenced by some of the secondary factors mentioned above.

DISCUSSION

Obviously, an answer to the question whether or not it is safe and wise to train an apparently left-handed child to write with his right hand cannot be unequivocal.

It has been pointed out that there are two entirely different kinds of handedness in early childhood: one is physiologic, native, inherent, inherited, and the other is psychologic, acquired, environmental, cultural. The first is the tendency — strong in some, weak in others — to prefer to use for more difficult manipulations a particular hand, which may be either the right or the left. Apparently, from a number of reports, this tendency is never absolute, but instead shifts normally from side to side throughout infancy and the early years of childhood, often with only a relatively slight and decidedly temporary preference for one or the other hand. In most infants, however, and for most of the time, Gesell reports that the right hand is more frequently used.

The second kind of handedness, in contemporary civilization at least, is the product of a steady, rather strong, social and cultural pressure favoring the use of the right side. There is no satisfactory explanation of why in the present day the right hand is always "right." One must accept that as a fact, although there are some indications that, in other times and civilizations, the left was the preferred side.⁹

In the older child and in the adult the eventual and permanent handedness appears to be the outcome of the merging of these two influences. Environmental pressure toward the right merely strengthens and confirms native right-handedness. When the inherent tendency is toward the left it comes into direct conflict with the environmental right. The result then seems to depend upon the relative strengths of the two opposing tendencies. When the inherent left preference is strong it is able to resist more or less completely the external pressure toward the right. This situation probably accounts for the majority of left-handed persons and for those who are left-handed with some right-handed skills. When the inherent left tendency is weak, it is largely or entirely overcome by the external right, producing persons who are either wholly right-handed or right-handed with some left-handed ability.

The groups of right-with-some-left and left-with-some-right are usually classed as ambidextrous. This is an ambiguous term with no very satisfactory definition. It is generally agreed that there is no

such condition as complete or absolute ambidexterity, in the sense that both hands are equally capable in all activities. All ambidextrous persons are right-handed in shaking hands, most are in eating, and some even are in writing. What is really claimed for them is that they choose the right hand for some activities and the left for others, or else that, although apparently right-handed or left-handed, they can perform most tasks better with the nonpreferred hand than the average person can. Consequently, except for the fact that the term is firmly imbedded in the language, it would be better to abandon entirely the classification of "ambidextrous" and replace it with such terms as right-with-some-left and left-with-some-right, which come much nearer describing the actual conditions.

It should by now be clear that the safety and wisdom of teaching an apparently left-handed child to use his right hand for writing depends upon the strength of his inherent preference for the left. If this preference is strong, or if for one reason or another he has become accustomed to use his left hand for all skilled acts, to force him to wield a pencil with his right may be difficult or even impossible. Conversely, if he is already using his right hand for some activities, he may probably be taught to write with it without difficulty.

It is only rarely that the question arises of shifting an older child from right-handed to left-handed writing. It should never even be considered unless he is strongly left in other activities, is having difficulty in expressing himself orally or on paper and is wholeheartedly ready and willing to try the experiment. A number of cases have been reported in which the shift was made with beneficial results, but they certainly are not common and the change should never be advised without considerable thought.

The chances of producing stuttering by teaching an apparently left-handed child to use pencil and pen with his right hand have probably been exaggerated. When stuttering does develop under these circumstances it is as likely to indicate an inherent weakness of the speech mechanism that causes it to break down under any added strain as it is to mean that the speech center has been partly shifted to the originally nondominant side of the cerebral cortex. The latter hypothesis is an attractive one, but it

has never been satisfactorily proved. The experience of many primary schools has shown that in most cases apparent left-handers learn to use the right hand for writing without suffering any disturbance of speech.⁹

CONCLUSIONS

Many apparently left-handed primary grade children may be successfully taught to write with the right hand. When writing begins they should all be so taught, because the use of the right hand fits in better with the left-to-right direction of writing and also because it conforms to the custom of the majority and hence is easier psychologically. If, however, a child objects strenuously or develops signs of nervous strain, of which stuttering may be one, the attempt should be abandoned at once, and he should be allowed to use his left hand without criticism.

Those who are taught to write with the left hand should be shown the proper position of the paper, which is slanted with the top border to the right instead of to the left as is usual. It is often necessary to drill them in the use of this position, since otherwise they are likely to imitate their right-handed neighbors. They should also be allowed to write with a slight backhand slant if they so prefer.

EPIDERMOID CARCINOMA PRIMARY IN BARTHOLIN'S GLAND

JOHN F CURRAN, SR, M D,* AND THOMAS V HEALEY, M D †

WORCESTER, MASSACHUSETTS

CARCINOMA of Bartholin's gland is one of the rarest malignant lesions occurring in the female genital tract, approximately 75 cases having been reported in the literature. In 1939, Simendinger,¹ with a detailed résumé of 38 cases, enumerated and classified the cases since Klob's² initial reference to the lesion in 1864. Isolated reports have subsequently appeared in the surgical literature,³ and Boughton,⁴ in a scholarly review of the problem in 1943, adjudged that by that time 75 cases had been listed, but that "a great number of these are published with inadequate data and may not be accepted as proved cases of Bartholin's gland carcinoma." Throughout such studies as have been cited and in more recent case reports,^{5, 6} there has occurred a major preponderance of adenocarcinomas as compared to epidermoid neoplasms. Furthermore, in Taussig's⁷ series of 155 cases of vulval cancer, only 9 originated in the vulvovaginal gland, similarly, in the files of the Worcester City Hospital, there are records of only 2 vulval neoplasms and 1 of the vestibular gland. Because of the relative infrequency and paucity of epidermoid types of tumor of this gland heretofore reported, we have been prompted to describe a case of epidermoid carcinoma primary in Bartholin's gland, which was recently treated on the wards of the East Surgical Service in the Worcester City Hospital under the supervision of one of us (J F C).

INCIDENCE

The incidence of this lesion has been established between the ages of forty to fifty-five years, whereas etiologic factors have been sought in chronic irritations and infections, trauma of sexual intercourse and tertiary syphilis.^{8, 11}

PATHOLOGY

Histologically, there are two types of carcinoma of Bartholin's gland: adenocarcinoma and epidermoid carcinoma. These forms are possible because the acini are lined by cuboidal cells, and the superficial ducts near the surface are lined with stratified squamous epithelium. The ducts lying between the acini and the superficial squamous-lined ducts are lined with a transitional type of epithelium, which readily undergoes metaplasia.¹²⁻¹⁴ Honan¹⁵ has expounded certain criteria necessary for a diagnosis of cancer primary in Bartholin's gland to be entertained. Extensive search of the literature reveals no special study of the lymphatics

that drain Bartholin's gland; they are generally considered to be the same as those from the vulva, with a predilection for the inguofemoral chains bilaterally because of the lymphatic anastomosis in the mons veneris.⁴ However, no cases of bilateral involvement of these glands have been reported. Such an extension to the inguofemoral nodes occurs with rapidity and prognosis is unfavorable, chiefly because early diagnosis is infrequent.¹⁶ A five-year-period without recurrence is not long enough to establish cure, since recurrence may take place ten to eighteen years after operation.¹⁷

SYMPTOMATOLOGY

The growth is sometimes first noted as a small, firm, nodular, painless swelling in the normal position of Bartholin's gland. At the beginning, it may be mobile, but later as the growth extends, it infiltrates the surrounding tissue and becomes fixed.¹⁰ Enlargement of the growth is attended by pain, which is commonly referred to the coccyx and groin and is made worse by coitus and menstruation. Walking may become painful, and a fetid leukorrhea with a serosanguineous discharge from the duct of the gland may develop. As the overlying skin becomes involved in the tumor mass, the growth becomes reddened, edematous and painful to touch. With continued progression there is a tendency for the mass to become necrotic, so that the tumor may feel fluctuant and may be confused with a cyst. The neoplasm tends to grow deeper rather than more superficially and involves the surrounding fat, the muscle tissue and, later, the pubic bones.

PHYSICAL FINDINGS

Usually there is a hard, nodular swelling situated to one side of the introitus, with an intact, overlying skin surface. The labium majus pudendi may be increased in size, especially in its posterior part. The tumor is felt in the portion of the labium corresponding to the normal site of the vulvovaginal gland, and it is usually lobulated on palpation. The mass is mobile and painless on pressure, and the suprajacent skin is normally free of the growth. There may or may not be inguinal adenopathy. Diagnosis is established by consideration of the possibility of carcinoma, failure of response to conservative measures and biopsy.

TREATMENT

Proper therapy of this disease appears to be a combination of irradiation and surgery,¹⁸ although

*Senior surgeon East Surgical Service Worcester City Hospital

†Assistant surgical resident East Surgical Service Worcester City Hospital

clinicians are not unanimous in opinion and no one surgeon's experience has been wide enough to outline a definitive course of treatment. Some advocate radical vulvectomy, including excision of the labia minora and clitoris by electrocoagulation supplemented by the extirpative inguinofemoral-lymph-node dissection of Basset bilaterally. Taussig¹⁹ recommends that this procedure be done in two stages: excision of the vulva, followed in two weeks by the groin dissections. Others reverse this order, employing the gland dissections first, always including removal of the so-called gland of Cloquet lying within the femoral ring in juxtaposition to the femoral vessels. Still others insist on preoperative and postoperative irradiation as a vital part of the treatment. Te Linde¹⁸ states that, in his opinion, irradiation should follow the radical operative procedures to give the patient every chance for recovery from a disease in which the prognosis, regardless of treatment, is poor.

CASE REPORT

L. H. (W. C. H. 371197), a 37-year-old divorced woman, was admitted to the hospital on April 16, 1948, with the complaint of "a small lump" on the right labium majus pudendi of about 5 years' duration. For the last year, the mass had been increasing in size and had of late been painful enough to cause her to seek medical advice in the outpatient department. Thence, she had been referred to the hospital with a presumptive diagnosis of "chronic Bartholin's cyst on the right." History elicited by the admitting house officer revealed that the tumor had been increasing in size of late, on two occasions had discharged bloody fluid and at times had caused pain in walking. There was no radiation of the pain, and the only other time the growth caused distress was if she inadvertently compressed it at toilet.

A review of the systems was noncontributory.

The menarche had begun at 11 years of age, the periods were irregular and of 7 days' duration without clots. Pain was marked for the first day. There was no intermenstrual discharge since an oophorectomy in 1938, the periods had occurred but once or twice yearly.

Physical examination revealed an obese woman with a pronounced alcoholic odor to the breath lying quietly in bed in no acute distress. There was a generalized psoriasis over the body. Physical findings of note were limited to the local examination: a firm, indurated, tender mass the size of a grape, situated to the side of the posterior fourchette in the position normally occupied by Bartholin's gland. No discharge could be expressed from the gland through its duct. The mass was tender, causing exquisite pain on palpation, and was reddish purple, with whitish areas shining through from deeper within the mass. It was nonfluctuant and mobile, although the overlying skin was firmly adherent. There was no demonstrable inguinal lymphadenopathy.

The temperature was 98.6°F, the pulse 88, and the respirations 20. The blood pressure was 136/82.

Examination of the blood disclosed a hemoglobin of 91 per cent and a white-cell count of 4800 with 66 per cent neutrophils, 4 per cent eosinophils, 1 per cent basophils, 26 per cent lymphocytes and 3 per cent monocytes. Blood Hinton and Kahn tests were negative. A chest film was unremarkable. The fasting blood sugar was 87 mg, and the nonprotein nitrogen 31 mg per 100 cc.

At operation on April 21 under nitrous oxide, oxygen and ether anesthesia a pelvic examination, precluded because of tenderness of the mass on admission, was performed without remarkable note. An elliptical incision was described about 0.6 cm around the cystic mass, which was then grasped with an Allis clamp and elevated. The mass was excised with intact overlying skin and a considerable amount of subadjacent areolar tissue. It was not possible to identify the duct to the gland.

The pathological diagnosis was epidermoid carcinoma (Grade II), primary in Bartholin's gland. The overlying skin was reported as normal and intact. The patient was seen in consultation by members of the Radiology Department, who believed that at this stage surgery should be relied upon solely to grant the patient a cure. A roentgenogram of the pelvis and pubic rami showed no evidence of metastatic involvement.

On April 30, under spinal anesthesia, the labia majora, mons veneris, clitoris and labia minora were excised generously with the cutting current of the electrosurgical knife. Hemostasis was secured with electrocoagulation and No. 4 to 0 catgut ligatures where needed. The skin was then sutured directly to the vaginal mucosa, and superiorly over the pubic arch, skin was sutured directly to skin in a vertical manner, although it was under some tension. An inflating Foley catheter was introduced to compensate for urethral edema and consequent urinary obstruction. Recovery was uneventful, the catheter being removed in 5 days with ensuing normal vesical function.

The pathological diagnoses were specimens consisting of labia majora, labia minora and clitoris and acute inflammation of recent incisional site.

At operation on May 14 under spinal anesthesia, a right-sided Basset operation was performed, with opening of the inguinal canal, removal of the round ligament, division of the inferior epigastric vessels and dissection for iliac, inguinal and femoral lymph nodes. No Cloquet node was detected, but several were removed from the iliac vessels. After operation, the patient was placed on anticoagulant therapy as a prophylaxis against femoriliac phlebitis, the blood prothrombin time being maintained at about 40 per cent of normal. The subsequent clinical course was without incident, and sutures were removed on the 9th postoperative day.

The specimen consisted of fascia and muscle tissue. The lymph nodes showed chronic lymphadenitis.

On May 28, under spinal anesthesia, a Basset operation was carried out on the left side as described above. Several lymph nodes were removed from the iliac chain, but again no Cloquet node detected. The patient was again placed on an anticoagulant regime for several days and convalesced without incident. The skin sutures were removed on the 7th postoperative day.

The specimen consisted of areolar tissue, fascia and muscle. The lymph nodes showed chronic lymphadenitis.

The patient was seen again in consultation by the Radiology Department, which preferred not to administer radiation but rather to follow the patient in the Tumor Clinic. Pelvic examination on the day of discharge showed an introitus readily admitting two fingers, with well healed suture lines. The patient was discharged on June 4, to be followed in the Tumor Clinic.

SUMMARY

A case of epidermoid carcinoma primary in Bartholin's gland is reported, and the literature on the subject is reviewed.

The epidermoid types of tumor of this gland are rare.

MEDICAL HAZARDS ASSOCIATED WITH THE FISH INDUSTRY IN MASSACHUSETTS

JOHN B SKINNER* AND CLARENCE C MALOOF, M D †

BOSTON

THE fish industry in Massachusetts is quite extensive and is to be found primarily near Cape Ann, in Boston and around New Bedford. The principal fish brought to these ports include cod, haddock, mackerel, herring, redfish, pollock, whiting, sole and flounder. The fish may be processed for sale in a number of ways. They may be sold in a fresh state round, dressed or filleted, they may be frozen whole, dressed or filleted, they may be prepared for canning, and they may be salted, although this treatment is becoming obsolete.

In the processes in which fillets are obtained, the fish is first descaled by passing through an inclined rotary tumbler with holes in the periphery. The descaled fish is filleted by workers grasping the fish by the head and cutting strips of meat from either side. The fillets are washed, packaged and frozen or packed into cans, which are capped, sterilized and washed in a cleansing solution to remove oil or fragments of fish.

The offal derived from fish is usually called "gurry" and is used primarily for the preparation of fish meal for chicken and animal feed, fish oils for animal feeding and industrial uses, and glues. The "gurry" consists of all portions unsuitable for eating, such as the head, fins, tails, skins, entrails and scales. Some of these manufacturing processes involve considerable handling of the "gurry," frequently with a resulting dermatitis.

One of the most serious health hazards in the fish industry is dermatitis. This falls into several categories. Although salt is used in salting fish and is usually handled with the bare hand, unless the worker is suffering from skin abrasions, it apparently does not cause dermatitis. The alkali used in washing the sealed cans to remove oil or fragments of fish occasionally causes skin irritation. However, dermatitis actually due to the handling

of the fish is mostly confined to the so-called "red-feed" dermatitis. This occurs only from June to September when mackerel are in season. The mackerel feed on minute crustaceans, one of the most common of which is "redfeed." The fish containing "redfeed" do not keep well after being caught. A few hours later the flesh of the fish opens, and after twenty-four hours the flesh is broken down to the spine. Hydrogen sulfide is rapidly evolved from such fish. The "redfeed," in addition to the digestive juice from the stomach of the mackerel, may cause a dermatitis to appear after one or two days' exposure. The skin, generally of the hands, becomes swollen and intensely red, with numerous superficial ulcerations. The areas affected are those in contact with the "redfeed" and occur chiefly along the palms and the sides of the fingers. Although the lesion is painful, it heals quickly upon application of mild soaks, such as boric acid or dilute epsom salts, followed by boric acid or zinc ointment, and avoidance of further contact with the material.

TUNA

The skin of the tuna is a thin, slimy membrane covering the scales, which can easily be scraped off and is said to contain a substance that is a primary skin irritant. It will cause dermatitis in anyone working for any length of time with ungloved hands.

REDFISH

Puncture wounds are extremely common when the workers handle redfish, which are usually filleted for quick freezing and principally sold in the Midwest. The worker grasps the fish in his left hand by the head, and with a stroke of the knife cuts off the boneless material on either side. Because of the fact that the redfish has numerous pointed bones extending back from its head, a puncture of the skin may occur if the fish is not held firmly. These puncture wounds are sometimes

*Director, Division of Occupational Hygiene, Massachusetts Department of Labor and Industries.

†Physician, Division of Occupational Hygiene, Massachusetts Department of Labor and Industries.

followed by lymphangitis and lymphadenitis, occasionally resulting in suppuration of the involved lymph nodes

ERYSIPELOID

A skin lesion frequently seen along the Atlantic Coast is erysiploid. It occurs primarily from contact with the "gurry" or the remains of any fish that has undergone putrefactive changes. In the handling of "gurry," abrasion, laceration or puncture of the skin is common, and erysiploid may result. This has been demonstrated to be caused by the organism *Erysipelothrix rhusopathia*. Of the 100 cases analyzed by Klauder,¹ 88 were occupational in origin, and 17 occurred in persons handling fish.

There is always a history of injury, and usually one of puncture of the skin by a fish bone. Erysiploid may develop within several hours to one or two days. The lesion is always on the hand and appears first at the site of puncture, where there is moderate pain followed by swelling and redness. The erythema progresses down the fingers into the web and frequently spreads along the adjoining finger. Swelling may be severe, interfering with function. Arthritic symptoms sometimes occur, and they may persist after the cutaneous lesions disappear. Lymphangitis is frequent, and many of the workers complain of pain and tenderness along the arm and forearm. Occasionally, there is a mild rise in temperature.

WEIL'S DISEASE

Another occupational disease experienced by fish cutters is Weil's disease or spirochetal jaundice.² The fish may become infected through the urine of infected rats. This disease is acquired through invasion of the organisms through the broken skin. After a varying period of several days or several weeks, the worker is aware of the onset of an acute illness characterized by chills, fever, headache, prostration and muscle and abdominal pain with nausea and vomiting. Inflammation of the eye frequently occurs, and jaundice with bleeding tendencies may appear after several days.

FISH OILS

Some workers develop dermatitis because they are allergic to fish oils. These cases are usually confined to those handling cooked fish in the canning departments.

OTHER CONDITIONS

In addition to exposure to the previously described infections, the workers are exposed to dampness, inasmuch as the fish are wet and in many cases the tables and floors of the workroom are con-

tinually wet. Exposure to dampness may result in neuralgic and rheumatic affections and may also be a contributing factor to respiratory infections. Where quick freezing of fish occurs, there is a potential exposure to refrigerants. In most cases, ammonia is used, and although the refrigerant is kept within a closed system, there is always the possibility of breaks in the piping. Ammonia is a highly irritant gas and is usually soluble in water and body fluids. It affects the upper respiratory tract, and consequently the workers immediately seek the out-of-doors when exposed to hazardous concentrations. However, if they are trapped in the room and cannot escape, they may develop a severe pulmonary edema.

In plants handling the "gurry" for conversion to animal feed, it is usually necessary to minimize the decay of the fish. In some cases, this is done by spraying the fish with chlorinated water. In other plants reliance is placed upon ozone to prevent this decay. In either case, the workers are potentially exposed to either of these two gases, which are lung irritants and should not be allowed to exist in concentrations greater than 1 part per 1,000,000 parts of air.

TREATMENT

The treatment of any of the above untoward effects is similar to that of any contact dermatitis or infection with resulting lymphangitis and lymphadenitis or pulmonary irritation with resulting pulmonary edema.

PREVENTION

The prevention of dermatitis from fish may be accomplished by the use of rubber gloves. These gloves should have treads on the finger tips to enable the workers to handle the slippery fish, or they should be covered with cotton gloves. A small amount of chlorine added to the water to wash the gloves has proved helpful in destroying contaminant organisms.

Where Weil's disease is experienced, elimination of rats is necessary. The use of protective clothing, boots and gloves minimizes skin contact with potentially infected material.

Where refrigerant gases may be encountered, the area should be well ventilated, and gas masks approved by the United States Bureau of Mines for protection against ammonia or other particular refrigerants should be available in handy locations for emergency use if leaks develop in the refrigerating system. The use of proper drains and floor boards will minimize the exposure to dampness.

MEDICAL PROGRESS

RUBELLA (GERMAN MEASLES) AND CONGENITAL DEFORMITIES*

CONRAD WESSELHOEFT, M D †

BOSTON

THE part played by rubella in the production of congenital deformities presents a serious problem in medical practice as well as in public health. The report by Gregg in 1941 of 78 cases of congenital cataract following maternal rubella aroused the attention of the medical profession to the dangers of this disease to the fetus in the early months of pregnancy. Since then numerous studies have been carried out confirming these original findings, as well as showing that other injuries to the fetus of equal gravity may ensue. Indeed, this virus appears to be capable of bringing about a pattern of defects in this early period of fetal life, consisting mainly of damage to the eye, ear, heart, teeth and brain, and these may occur singly or in combination. The entire subject of rubella was discussed, including its history, pathogenesis and differential diagnosis, in a progress report¹ in 1947. The purpose of this paper is to present subsequent material dealing with congenital defects and to bring the subject matter up to date.

At the outset it is well to recall that rubella is a disease entity unrelated to measles, and that one attack usually confers a lifelong immunity, although second attacks may take place. No vaccine is as yet available. Drugs and antibiotics exert no influence on the virus. The diagnosis rests on those characteristics that differentiate this malady from the other exanthems—namely, the absence of Koplik spots, the kaleidoscopic character of the rash, the presence of palpable lymph nodes behind the ears and not infrequently a pink suffusion of the whites of the eyes, in contrast to the sticky mucopurulent conjunctivitis of measles. All these features are variable, depending on the severity of the disease. The circumstantial evidence of a known exposure coupled with an incubation period of approximately eighteen days is always helpful in diagnosis. The rare complications—polyarthritides, thrombopenic purpura and encephalitis—are not considered here, because neither the severity of the disease nor its complications appear to have any bearing whatever on the incidence or severity of congenital deformities. The complications that are concerned here are those of

rubella during pregnancy, and are the results of injury to the fetus in utero.

MISCARRIAGE

The virus of rubella has been isolated from the blood in the early stages of this disease. Therefore, when a pregnant woman is attacked by rubella the virus appears to be capable either of finding its way through the placenta to the fetus or of disturbing the fetal metabolism. Thus, in one way or another, certain peculiarly susceptible tissues may suffer injury. The fetus may die promptly or linger along and die several months after the attack. Death of the fetus early in pregnancy frequently results in the spontaneous emptying of the uterus. When death of the fetus occurs in the later months of pregnancy, the uterus is not so ready to empty itself and may continue to retain the dead fetus for some time without any apparent injury to the mother. Just how often spontaneous miscarriage takes place in the course of maternal rubella is unknown. Two cases in which the attack of rubella occurred in the second month with spontaneous abortion in the third month have already been reported,¹ and to this I can add a similar one. In a fourth case, in which the attack was in the second month, the patient was delivered of a macerated fetus in the seventh month.

Swan and Tostevin² reported a miscarriage in the third month following rubella in the second month of pregnancy. Goar and Potts³ described one stillbirth at seven months after an attack in the first month. Fox and Bortin⁴ discussed a stillbirth at the seventh month following rubella in the first month of pregnancy. Ober, Horton and Feemster⁵ reported 9 pregnancies that terminated in abortion or stillbirth in which the attacks of rubella were in the first four months of pregnancy in 7 cases. Indeed, in this survey conducted for the year 1943 in Massachusetts there were as many abortions and stillbirths uncovered as there were defective children. Swan⁶ has recently reported 15 cases of stillbirth following rubella, in 13 of which the infection took place within the first four months. The sum total of these reports comprises 31 abortions or stillbirths following rubella, 27 of which occurred after an attack in the first four months of pregnancy.

*Presented at the Annual Meeting of the Massachusetts Medical Society May 27, 1948.
From the Harvard School of Public Health and the Haynes Memorial, Massachusetts Memorial Hospitals.

†Clinical professor of infectious diseases, Harvard School of Public Health.

I am firmly convinced that any effort to prevent miscarriage during or after an attack of maternal rubella is misdirected energy, since it is not in the best interest of the mother, to say nothing of the best interest of the fetus if it is alive. To my mind, the signs and symptoms of threatened miscarriage during or after an attack of rubella should be looked upon with favor. Consultation with and confirmation by a second physician, together with the

developed gross dental defects. To this can be added 21 gross defects reported in the literature (Table 1).

NORMAL CHILDREN BORN OF MOTHERS WHO CONTRACTED RUBELLA DURING PREGNANCY

There have been reported 36 additional normal babies born of mothers who suffered an attack of rubella during pregnancy: 11 in the first, 17 in the

SEVERE CONGENITAL DEFECTS FOLLOWING RUBELLA IN PREGNANCY

In the progress report mentioned above I recorded from the literature 521 major congenital defects after an attack of rubella in pregnancy, as

second, and 8 in the last trimester. This gives a total of 656 defective infants as against 124 normal babies, a ratio of 5 to 1 (Table 2).

As pointed out in the previous progress report, this figure cannot be taken as the true ratio of grossly defective infants to normal babies of mothers who had rubella in pregnancy. The two sets of figures are obtained without relation to each other. Therefore, the ratio cannot be construed

against 52 reports of normal babies following this disease in pregnancy.

Since then the first quarterly report of the committee appointed by the National Society for the Prevention of Blindness and the American Academy of Pediatrics⁷ gives the following additional data on 132 mothers who had rubella during the first trimester of pregnancy. Among these there were 18 normal babies. Seventy-six babies had congenital cataracts, 35 were completely or partially deaf, 67 had congenital heart lesions, 46 were mentally retarded, there was 1 cretin and 1 mongolian idiot, and 22 were microcephalic. Two

as the risk. Nor can the risk be properly calculated on the basis of reported cases, since it has been estimated that only 14 per cent of cases are reported¹⁵ and congenital deformities are not reportable. The backward approach to this whole subject renders any mathematical calculation open to serious objection. The total score presented here merely represents a danger to the fetus when rubella occurs in the course of pregnancy—a danger that apparently is greatest in the first trimester as was clearly brought out in the first report of Swan et al.,¹⁶ and confirmed by subsequent reports.

It has been shown that congenital cataract of the central and nuclear type and certain congenital anomalies of the heart, such as interventricular septal defects, result from defective development in the first trimester.^{1, 17} Mongolism follows arrested development taking place between the sixth and ninth weeks.¹¹ Thus, the stage of development of the fetus at which the agent is active determines the type of injury that may take place. The records of the cases of congenital defects following rubella in pregnancy when the time of the attack of rubella is given in relation to the stage of pregnancy are in agreement with this knowledge of embryology established prior to 1941 and in conformity to more recent studies with trypan blue, which does not reach the fetus.¹⁸ An interesting feature in all this speculation is that maternal rubella just prior to conception,¹ as well as an injection of trypan blue to the mother rat prior to conception, can result in congenital deformities.¹⁸

Thus, the virus in maternal rubella in some manner, either directly or indirectly, shows a predilection for injuring certain tissues in the fetus according to the stage of fetal development. It is not understood just how the arrest of development in these organs is brought about although much theorizing is done on this subject. The fact that damage takes place in accordance with known embryologic expectancy offers supportive evidence that one is dealing with an agent that can produce predictable consequences. However, as in other infections there is always the unpredictable element of the resistance of the tissues in the host, which allow of great variability in the injury done — from complete escape to multiple serious injuries and even death. Thus, the predictable consequences of maternal rubella on the fetus are merely possibilities, which become more likely according to the age of the fetus at the time of the rubella attack. So far as the first four months of fetal life are concerned the information to date suggests a very real danger that maternal rubella may result in a serious congenital defect.

Therapeutic abortion is immediately challenged by two objections. The first is that insufficient data are at hand to warrant considering therapeutic abortion. The figures obtained by Fox and Bortin⁴ and Ober et al.⁵ purport to show that the risk of congenital deformities is much less than one gathers from other surveys and the total reported congenital deformities and normal births following rubella. As already stated, these data are obtained from records that are too imperfect to be reliable. The evidence against rubella, though largely on an empirical basis as yet, is sufficient to make one aware of a danger to the fetus in early pregnancy. This danger to the life of the fetus is not nearly as disastrous in its consequences as it is to the welfare of the family in the event of survival with gross congenital deformities.

The second objection is that therapeutic abortion, except to save the life of the mother, is not permissible by law in Massachusetts. The legal aspects of this situation were discussed at length in the previous progress report.¹ The statutes regarding abortion vary in different states, and not only has the fundamental law undergone changes whereby a later proviso permits a therapeutic abortion to save the life of the mother but also judicial opinion regarding this proviso offers a broadened interpretation to permit the emptying of the uterus beyond the danger to the mother's life. The law and medicine are subject to change in social evolution. The purpose of both is to protect and benefit mankind. Consequently, when some new development in the knowledge of medicine reveals any legal obstruction to the carrying out of a desirable preventive measure for the benefit of mankind due consideration should be given to the enactment of modifying statutes to meet the situation.

It is of the utmost importance to stress the fact that the birth of one of these grossly deformed babies is not simply a disaster to the individual child but that such a grossly deformed child tends to blight the life of the entire family. The mother has to give so much attention to this child that she becomes worn out in body and mind. As a result of this the other children in the family fail to get proper care. Furthermore, social-service follow-up studies show that the parents of such a defective child are often afraid to have any more children, even when it is explained to them that this will not happen again. They say that they just could not take on the care of another infant — even a healthy one. This attitude is expressed in various economic walks of life. In short, the arrival of a grossly defective child in a family not only brings unhappiness and sorrow but also definitely inhibits childbearing.

With all this in mind the medical profession must give attention to the danger of rubella in early pregnancy. It behooves physicians to investigate this problem with the same zeal that is being shown today in the study and control of other diseases. The fear of a crippling disease such as poliomyelitis makes it possible to arouse the interest and generosity of the public. The accumulation of evidence against rubella as a cause of gross congenital deformities is capable of arousing fear similar to that of poliomyelitis, and like poliomyelitis, the basis of this fear is not of death but of the serious crippling defects. It seems, therefore, that the medical profession must through its own initiative and with the support of public opinion take up this problem of rubella in a concerted drive under a national commission, rather than by sporadic local investigations. The results of such a national investigative organization would in the course of time evaluate the dangers of this disease in their true light with satisfactory figures. Along with this would be well conceived investigative work directed

toward the possibility of widespread immunization. Until work of this kind is carried out on a national scale physicians must face the problem as it lies before them today.

First of all, it becomes obvious that it is advisable for everyone to have rubella in childhood and thereby to acquire a relative, lifelong immunity. This proposition is all very well, but many children have mothers who have never had the disease and who are in the first months of pregnancy. Therefore, to encourage the spread of the disease in childhood may well increase the incidence of the disease among these pregnant mothers. Consequently, the only satisfactory solution will be an immunizing agent that does not carry with it the infectiousness of the disease itself. This has already been successfully accomplished in two virus diseases—namely, smallpox and yellow fever.

In the second place, pregnant mothers should avoid exposure to rubella. This is likewise beset with difficulties because rubella is infectious before the rash appears. For example, in the case of a woman in the first four months of pregnancy with a negative rubella history who has spent the afternoon with a friend who comes down the next day with a typical rubella, would gamma globulin do any good as a preventive measure? Theoretically, one might expect some benefit, but unfortunately gamma globulin is made from pooled blood very weak in antibodies to rubella in contrast to its content of measles antibodies. Ordinary gamma globulin has not proved effective in preventing rubella, mumps or chicken pox. The Massachusetts Department of Public Health urges physicians not to use gamma globulin except for diseases in which it has proved to be efficacious. In the case alluded to, the administration of 10 cc of gamma globulin offers only a remote possibility of protection. If the pregnant mother already has rubella, it is hardly likely that any antibodies contained in the gamma globulin could be relied upon to protect the fetus. To my mind, in the light of present knowledge of gamma globulin, its use under these circumstances offers a false sense of security.

Barring the favorable event of a threatened miscarriage, which can lead to spontaneous or surgical emptying of the uterus, physicians in Massachusetts are placed in a medicolegal dilemma. The use of

contraceptives for the prevention of disease is permitted by law. The idea of a second amendment to the law, which would permit a therapeutic abortion for the prevention of the birth of a diseased child, seems to deserve equal consideration in the interest of public health.

If all cases of rubella were reported—as they should be—and especially those in pregnant women with a note to that effect, the epidemiologic status of this disease would be better ascertained than at present, and the attendant risk of gross congenital deformities could then be satisfactorily determined. The anxiety caused by the evidence at hand regarding the danger of maternal rubella to the fetus demands that the medical profession report all cases of rubella with the utmost diligence and that the results of maternal rubella on the fetus be studied on a nation-wide basis.

CASE 35071

PRESENTATION OF CASE

First admission A forty-six-year-old carpenter was admitted to the hospital because of epigastric distress of eight years' duration

The pain usually developed in the midafternoon and was promptly relieved by food or soda. On one occasion he vomited large quantities of bright blood.

Physical examination revealed a well developed man, with a blood pressure of 130 systolic, 80 diastolic. There was moderate exophthalmos and slight lidlag. The skin was slightly dry and cool. Examination of the chest and abdomen was negative. Urine, blood and stool examinations, including guaiac tests, were negative. Gastric analysis revealed 33 units of free hydrochloric acid. The serum cholesterol was 153 mg per 100 cc. A gastrointestinal series showed a small ulcer crater on the lesser curvature of the stomach just above the angulus. Basal metabolic rates on six occasions ranged from -30 to -40 per cent. Electrocardiograms showed bradycardia and low T waves. Three weeks of medical management brought symptomatic relief but produced little change roentgenologically in the gastric ulcer. He was discharged to the Out-Patient Department on a bland diet and alkali therapy.

Second admission (five years later) In the interim the epigastric distress was well controlled, and the patient failed to return to the Out-Patient Department. He had continued the discharge medication of 0.1 gm of desiccated thyroid and followed the diet rather faithfully. Nine months before this admission he gradually developed crampy, midepigastric pain about one hour before meals, which was not relieved by food or alkali.

Physical examination was essentially unchanged. The blood cholesterol was 417 mg per 100 cc. Basal metabolic rates again ranged from -39 to -46 per cent, and the protein-bound iodine was 0.4 microgm per 100 cc. Two gastrointestinal series again demonstrated the small lesser-curvature ulcer. Barium enemas and skull films were normal. He

was placed on a six-meal bland diet and 0.2 gm of thyroid daily, with considerable improvement, and was again discharged.

Third admission (one year later) He was fairly comfortable for three or four months, but then he became plagued again by his epigastric pain. Three weeks before entry he abruptly developed a tender swelling of the thoracic spine, which persisted unchanged. The only changes on physical examination were midepigastric tenderness and a tender, smooth swelling over the tips of the sixth and seventh dorsal vertebrae. The urine was normal except for 4 or 5 white blood cells per high-power field in the sediment. The white-cell count was 8650, the hemoglobin was 14.5 gm. The cholesterol was 192 mg and the esters 146 mg per 100 cc, and the calcium and phosphorus were normal. A gastrointestinal series again demonstrated the ulcer, which was slightly smaller than before. There was osteoporosis of the spine and a compression fracture of the ninth dorsal vertebra. Examination of the lungs and intravenous pyelograms were not remarkable.

A subtotal gastrectomy, with removal of a benign ulcer, was done. The patient convalesced well until the seventh postoperative day, when he developed right-upper-quadrant pain following meals and worse at night. On the eleventh postoperative day he abruptly passed a thin, bright-red, bloody stool and another an hour later. The pain, which had been intermittent and crampy at onset, became sharp and steady. Abdominal examination was negative, as were plain films of the abdomen. The abdomen was re-explored, with entirely negative results. He again convalesced well without pain or bleeding until the seventh postoperative day, when the upper-quadrant distress returned and was again apparently closely related to food, coming on ten to twenty minutes after eating. This was associated with nausea, a sense of abdominal fullness and dyspnea. After several days this syndrome was expanded to include an urge to defecate, with passage of thin, loose stools immediately after the pain began. These symptoms became quite incapacitating, and the patient failed to eat and gain weight. A gastrointestinal series showed the stump of the stomach to fill well and empty readily, with no demonstrable lesion. A serum amylase was 60 units. The pain was only partially relieved by atropine and demerol, and he consistently refused to eat because of the pain. After almost two months in the hospital at his own request he was discharged on a six-meal bland diet, atropine and phenobarbital.

Final admission (six weeks later) His condition after discharge became increasingly poor. He practically refused to eat at all because of the epigastric distress, nausea and diarrhea, which invariably followed eating even the smallest amount of food. The pain came in waves, was accompanied

by loud gurglings and lasted about one hour. He became emaciated and developed dyspnea, dizziness, palpitations, sweating and flushing, which occurred erratically in time, lasted only a few minutes and was not necessarily associated with the other complaints. He also noted grossly bloody stools on several occasions.

Physical examination revealed a tired, weak and emaciated man. The skin was dry, inelastic and warm. The chest was clear. There were numerous extrasystoles. The abdomen was slightly distended, with moderate tenderness just to the right and below the umbilicus. Peristalsis was active with occasional high-pitched gurgles. Rectal examination showed tenderness on the right side, but no masses could be felt.

The pulse was 45, and the respirations 20. The blood pressure was 105 systolic, 55 diastolic.

The urine was cloudy, with a specific gravity of 1.018. Albumin and sugar tests were negative. The sediment was loaded with white blood cells but no red blood cells. The blood hemoglobin was 15.5 gm. The white-cell count was 6250, with 59 per cent neutrophils. The stool was light tan and guaiac negative. The amylase was 25 units, and the total protein 5.86 gm per 100 cc, with an albumin-globulin ratio of 1.5, the nonprotein nitrogen was 24 mg per 100 cc. The van den Bergh reaction was 0.4 mg per 100 cc direct and 0.7 mg indirect. The prothrombin time was 20 seconds (normal, 16 seconds), the cephalin flocculation test was + in twenty-four and ++ in forty-eight hours. The cholesterol was 176 mg per 100 cc. The basal metabolic rate was -40 per cent and remained at this level despite intravenous administration of thyroxin. A gastrointestinal series showed barium to enter the stump of the stomach and pass readily into the efferent loop. There was no evidence of obstruction or marginal ulceration.

Numerous diagnostic studies were instituted in attempts to elucidate further the nature of the disorder, but the patient's course was little affected by the procedures tried. The appearance time of indigo carmine was five and a half hours. A glucose tolerance test showed a fasting blood sugar of 96 mg per 100 cc, with a rise of 137 mg in half an hour. The levels at one, two, three, four and five hours were 126, 111, 78, 69, and 72 mg per 100 cc, respectively. A vitamin A tolerance curve showed a fasting level of 1.3 units per cubic centimeter, and there was no rise at all in the subsequent specimens. A right splanchnic block (sixth to twelfth dorsal segments) with procaine was done, which diminished somewhat the pain during the period of anesthesia but did not relieve the tenderness. A differential spinal block was attempted, and with loss of pinprick sensations to levels of the second dorsal segment he was able to drink milk without pain, but the sense of distention and fullness was not altered. He continued to starve himself because of the severe

symptoms initiated by ingestion of food, and his condition deteriorated rapidly.

An intensive program of tube and intravenous feedings was undertaken, but he tolerated the tube feedings poorly, and they were discontinued. An abdominal exploration and feeding jejunostomy was done. No abnormalities were made out at the time of exploration. Postoperatively he continued to have the same severe midepigastic pain and marked nausea and vomiting. On the fifth postoperative day he began to vomit blood, and sero-sanguineous material exuded from the jejunostomy wound. He developed abdominal distention and diffuse abdominal tenderness. The blood pressure dropped to 60 systolic, 40 diastolic, and there were practically no peripheral pulses. He remained in a shock-like state throughout the day despite supportive measures and died quietly late that night.

DIFFERENTIAL DIAGNOSIS

DR ARTHUR W ALLEN I would like to have someone tell me whether the cholesterol esters (146 mg per 100 cc) were within a normal range.

DR CHESTER M JONES That is about normal.

DR ALLEN Thank you.

What about the vitamin A?

DR PERRY J CULVER It is a slightly high level. This indicates absorption and rise after a dose of vitamin A.

DR ALLEN I would like to see the x-ray films. It is a long case and a very complicated one, and unless I can get some help here I am not going to be able to tell what was the matter with this man.

DR STANLEY M WYMAN I do not know how much of the original examination to show, Dr Allen. These first two gastrointestinal examinations demonstrated in essentially the same position a crater just above the angle, which by x-ray examination appears grossly benign. As you recall, the benign character was confirmed at the time of the subtotal gastrectomy. He has a calcified aorta, which is unusual for a man of this age.

DR ALLEN Are there any esophageal varices?

DR WYMAN No, but he does not have a large spleen. Without splenomegaly varices would be quite unusual.

This film demonstrates the calcified abdominal aorta a little better, which is distinctly premature for a man of this age. The film of the thoracic spine, taken because of the swelling over the sixth spinous process, shows a compression fracture of the ninth thoracic body. The bones are quite osteoporotic for a man of forty-six, and one can see the dense calcification of the aortic arch — again, an unusual finding.

The first films of the stomach and upper gastrointestinal tract taken postoperatively show the stoma to be of good width. There is diffuse thickening of the gastric folds, but I cannot identify any evidence of ulcer at the stoma or other evidence of localized disease.

DR ALLEN Is there active peristalsis?

DR WYMAN Just a little overfilling of proximal small bowel because the barium ran through to the jejunum so rapidly

DR ALLEN Is this the afferent loop?

DR WYMAN It must be This shows a fairly normal transport of barium at the time of the examination, the barium reaching the ileum in about three hours The most striking thing, to my mind from these films, is the presumptive evidence of premature senility in a man of forty-six The osteoporosis of his bones, the arteriosclerosis and his chest all make him look considerably older than the age of forty-six or even fifty This film shows a slight increase in the anteroposterior diameter of the chest and degenerative changes in the thoracic spine with moderate osteoporosis, and the heart itself is not remarkable except that the aorta is calcified

DR ALLEN This is a very complex problem, and this man was prematurely old as demonstrated by the advanced arteriosclerosis and so forth Also there was an extraordinary persistence of a very low metabolic rate, even in spite of thyroid therapy That is very unusual I do not know how to explain it At one time the pulse was recorded at 45 His story gives me the impression of a hibernating animal, with his ability to subsist on a small amount of nourishment for an unusually long period in a situation that probably would have produced a fatal outcome much more quickly in the normal person There are many things about this that I do not understand I am not sure what other conditions could produce such a persistently low metabolic rate I am inclined to think that it was correctly recorded Obviously, the examiners were quite interested in the low metabolic rate, and the protein-bound iodine was, according to Dr Cope's information, which he was kind enough to give me, quite low and consistent with the low metabolic rate at that time

The long duration of the ulcer symptoms is a pretty good indication that he had a benign lesion rather than a malignant one He did very well with this ulcer, though it apparently never healed The change in the type of pain, which had previously responded to food and alkalis, suggests that perhaps something else was developing—something that also caused epigastric distress, but no longer of a type relieved by food and alkali It might be fair to assume that perhaps this new development was not related to the lesser-curvature ulcer

I do not know why the skull films were done, but they bring to mind the possibility of some cerebral lesion such as that described first by Dr Harvey Cushing¹—the association of lesions in the midbrain with ulcerations in the duodenum and in the stomach I do not believe that is a very likely possibility here, but it came to mind when I read this report

The osteoporosis is interesting, and taken with the spontaneous fracture of the ninth dorsal vertebra, makes me wonder whether it was simply dietary or whether there was some basic underlying metabolic disturbance that is not clear to me I do not know what the explanation would be This one instance of high recording of blood cholesterol, I think, might be a typographical error It is listed at 417 mg per 100 cc while every other one (and many others were done) was in a normal range

DR JACOB LERMAN It was before treatment

DR ALLEN That is the only time, before treatment, that we get any such level

The operation performed, I suppose, was a subtotal gastrectomy, with doubtless removal of the distal half or two thirds of the stomach, including the ulcer on the lesser curvature There is nothing unusual about that It was undoubtedly assumed that the bleeding experienced previously originated from the ulcer Then when he bled on the eleventh postoperative day the surgeons were disturbed because they wondered if it had anything to do with their suture line or whether they had overlooked some other lesion Of course, it is possible for a man to have an ulcer in the stomach and duodenum as well, and the ulcer in the duodenum might be far enough down so that the duodenal stump can be turned in without too much awareness of the situation on the part of the surgeon

The change in the character of the pain nine months before he came in the second time makes me believe that he did have something besides this ulcer of the lesser curvature The fact that he bled after resection, as late as the eleventh day, makes me believe that he bled, not from the suture line, in which case bleeding should have taken place about the seventh day or earlier, but from a lesion, whatever it was, that produced a change in symptoms and may very well have been related to the final outcome The fact that he was re-explored and nothing found wrong with the anastomotic site and no cause for the pain determined makes me wonder if this man had a lesion that could not be found within the abdomen by ordinary methods Could he have had a hidden lesion in that portion of the duodenum that cannot be seen readily without opening the mesentery over it, or could the bleeding have come from above?

The symptoms described here suggesting the dumping syndrome are interesting, but I am not of the opinion that this man could have had such a severe course, with the outcome as it was, on the basis of a dumping syndrome alone In some gastrectomized patients, the percentage is low, there is too rapid emptying of the stomach segment into the jejunum, with the symptoms described here—discomfort, usually called distress in the epigastrium, nausea and sweating that last for variable periods of time and usually go away about thirty minutes after the ingestion of food, particularly

if the patient lies down. The postoperative symptoms in this man were more severe than that. They were so severe that he did not dare take any food at all, because it initiated a gastrointestinal reflex, which was very marked, giving a five-and-a-half-hour time from the ingestion of carmine to the discharge of the dye from the rectum. That is a very rapid intestinal rate. Doubtless it is on that basis that the various tests were done on the parasympathetics and with spinal anesthesia.

A feature about this case that is disturbing and that I cannot understand is why this man had tenderness in the right lower quadrant. I cannot see why he should have right-lower-quadrant tenderness just on the basis of his rapid intestinal rate. It is conceivable, I suppose, that he did have a lesion in the cecum, but all the examinations with barium enema prior to operation failed to reveal any difficulty in the right colon.

The whole situation is further confused by the fact that, if I am interpreting this correctly, this man died of hemorrhage. It is very unusual to die of hemorrhage these days. There is usually enough blood around and it keeps going in and usually death can be staved off for an incredible length of time by that means. This man on his final day, being in a poor nutritional state, began to bleed and serosanguineous material came from the jejunostomy tube. He developed abdominal distention, with diffuse abdominal tenderness. It does not state whether he still had peristalsis. One might like to know that because, even in a man as sick as this, if we assume that all he did was to bleed to death, I think he still would have had peristalsis. If he had peritonitis, however, he would not have peristalsis. The fact that the man vomited blood and blood came from the jejunostomy tube probably rules out a source of hemorrhage lower than the high jejunum — that is, we must look for something from the esophagus, from the stomach, from the duodenum or from the first portion of the jejunum.

I wonder whether that is a fair deduction — whether or not he had something else. I am not prepared to say where the bleeding came from. We have these various sources of bleeding that we know about, — the esophagus, usually esophageal varices, and lesions in the stomach of all kinds, — but it is hard to believe that he could have had leiomyoma or cancer of the stomach or ulcer of the stomach that would not have been palpated at the last exploration. He could have had gastritis, I suppose. People have bled to death from gastritis alone. We have at least 2 cases in this hospital in which that has occurred. He could, I suppose, have had duodenal ulcer far down that was never felt and never demonstrated, from which he could have bled. He could have had a diverticulum of the duodenum, which was not picked up on x-ray examination and not seen at exploration. He could have had in that

duodenum gastric mucosa from which he could have bled. An ulcer could also have perforated finally into the peritoneal cavity, resulting in peritonitis.

DR TRACY B. MALLORY: There is a note that in the final three hours peristalsis was minimal and sluggish.

DR ALLEN: Still present?

DR MALLORY: Apparently.

DR ALLEN: That would make it necessary for me to believe that this man bled to death from whatever lesions he had. I do not think we should forget the pancreas. He had had at one time slight elevation of the serum amylase. I doubt if pancreatitis would have lasted as long as this. The necrotizing type of pancreatitis causes death in the neighborhood of forty days, and erosion of the splenic vessels sometimes occurs with perforation into the colon or stomach, resulting in death by that route. It could, I suppose, have eroded into the duodenum or the jejunum, and the blood might have come from some such source. I doubt that we have enough evidence to back up erosion of the splenic vessels from pancreatitis.

Now, of course, I do not know how far general systemic disorders could have played a role in this case. It might be something that I have never heard of. At any rate, I must get through because I know a lot of you want to discuss it. This man had a gastric ulcer. We assume that he had hypothyroidism and marked arteriosclerosis, and he had a compression fracture of the ninth dorsal vertebra on the basis of osteoporosis and extreme malnutrition. Of all the things I can think of that satisfy me as to the final cause of death and the source of all his bleeding, a lesion in the third portion of the duodenum, which I am going to assume was probably a diverticulum, is the most probable.

DR MALLORY: This patient puzzled everyone in the hospital as much as he has Dr. Allen. Almost everyone saw him and made a note at one time or other.

DR COPE: Have you anything to say?

DR OLIVER COPE: No one thought of Dr. Allen's diagnosis. We should have considered it, practically everything else was considered. The Pathology Department did one kindness to Dr. Allen. They left out some of the data that attracted attention way out in left field. In addition to hypothyroidism, the question was brought up as to whether he might have hyperparathyroidism. Dr. Allen referred wisely to metabolic disturbances that might have given rise to the ulcer. We debated this back and forth, for there was a suggestion that he had hyperparathyroidism and coincidental ulceration in the upper intestinal tract. It was a good thought, but no one could make the diagnosis.

No one could understand why he had the pain, and I think it was fair to summarize the clinical opinions as follows: there was a suggestion of hyper-

parathyroidism, which was excluded because the evidence (I will not go into the data in detail) was equivocal, perhaps because the patient did not respond to thyroid. Dr Lerman will talk about the response to thyroid in a moment.

The neurosurgeons could not explain why he had pain. They thought that the only way to prevent pain was to go to the highest center—in other words, to do a lobotomy. The lobotomy would also have helped in the management, for the patient was suspicious and extremely difficult to handle. The Medical Service did an extraordinary job in keeping him alive. He required an enormous amount of care for four months throughout which he was in an extreme state of malnutrition. Finally, another point of view, which was the point of view adopted, was to re-explore the abdomen as a final measure on a chance that some lesion had been overlooked—the type of lesion Dr Allen referred to. Such an exploration was recognized to carry a high risk in a patient in such a condition and particularly since no one had any firm idea of what might be wrong. Exploration was carried out by Dr Welch.

DR LERMAN: I think there is no doubt about the diagnosis of myxedema. On the first admission the diagnosis was suggestive. When he came back the second time it was very obvious. Of theoretical interest is the possible etiology. He did have signs of residual exophthalmic goiter. The question arose whether it could be a rare type of hyperthyroidism that had burned out, with resulting myxedema. He responded to a special preparation, which we were using, called tetrabromthyronine. The statement is made that he did not respond to thyroxine. That is not true. The response was poor, but he did respond at one time to a dose of 1 mg of thyroxine for ten days when the basal metabolic rate went from -40 to -25 per cent, which is a poor result. The explanation for the response was that he was in such a poor nutritional state that he could not get up enough steam to make a response. It is interesting to speculate on the relation between prolonged myxedema and arteriosclerosis. It seems reasonable to expect that the hypercholesterolemia of myxedema will lead to extensive atherosclerosis in large and small vessels.

DR JONES: When I saw him several times at the request of the surgeons, it seemed to me justifiable to explore again, even in the absence of any positive findings, because of the intensity of the pain. It was directly connected with food. It was repeated over and over again, I am sure it was not a dumping syndrome. The pain was too severe for that. The main thing was that he did have a real intra-abdominal disease. We did not think he had an ulcer, as a matter of fact—at least, I thought he did not. I thought it was possible that he had a kinking with some obstruction by which pain was produced by peristalsis from time to time after

intake of food, and we decided that the only way to help was to go in and explore again, trying to find a lesion that might be treated.

DR CLAUDE E. WELCH: His outstanding symptom was pain. We thought that cancer of the pancreas would be the most likely diagnosis, but we really expected to find nothing. We found nothing.

DR ALLEN: I would like to add one thing. I did not mention the possibility of an anastomotic ulcer because of final bleeding. It is extremely unusual if it ever occurs following a gastrectomy for a gastric ulcer.

CLINICAL DIAGNOSES

Abdominal pain of unknown etiology
Myxedema
Arteriosclerosis

DR ALLEN'S DIAGNOSES

Gastric ulcer, postoperative
Osteoporosis, with compression fracture of ninth dorsal vertebra
Arteriosclerosis
Hypothyroidism
Duodenal diverticulum

ANATOMICAL DIAGNOSES

Atrophy of thyroid gland, with myxedema
Arteriosclerosis, severe, of aorta and mesenteric vessels
Congenital anomaly of mesenteric arteries, hypoplasia of celiac axis and hypertrophy of superior mesenteric
Thrombotic occlusion, old, of celiac axis
Thrombotic occlusion, fresh, of superior mesenteric artery
Incipient gangrene of small intestine
Osteoporosis
Slight hyperplasia of parathyroid glands

PATHOLOGICAL DISCUSSION

DR MALLORY: At autopsy in this case, the lesion found was in the mesenteric vessels. He had what I am quite sure was an anomaly to start with. The celiac axis was very small, and the superior mesenteric artery very large. The inferior mesenteric was also small, but I would assume the celiac axis was half normal diameter and the superior mesenteric was twice normal diameter. The celiac axis was almost completely occluded by an old, organized thrombus, and a large anastomotic vessel was found connecting the superior mesenteric and pancreaticoduodenal arteries. The stomach and spleen must have been nourished from the superior mesenteric artery through various anastomoses. The terminal episode was an acute thrombosis of the superior mesenteric, which had cut off the blood supply of almost the entire intestinal tract between

the esophagus and the colon. It was partially infarcted. At autopsy we found no intrinsic lesion in the remainder of the stomach or elsewhere in the intestinal tract. So I think the sclerotic changes in the mesenteric vessels probably were the cause of the persistent pain. At least, we have no other explanation for it.

A few other findings at autopsy were interesting. The thyroid gland was almost completely atrophic, and in numerous sections we were able to find only four or five recognizable thyroid acini. The rest was reduced to fibrous tissue. The parathyroid glands seemed slightly hyperplastic. Certainly, the proportion of parenchyma to fat cells was increased, but because of the emaciation the ratio may have been disturbed by loss of fat cells. The pituitary body was normal.

DR JONES: This could be explained, it seems to me, on the theory that the patient had a minimal local blood supply, and the minute one increased the demand for blood by putting in food, the local blood supply was inadequate and it caused "anginal" pain.

DR MALLORY: The abdominal aorta was extraordinarily sclerotic, as shown in the x-ray films, and the atheromatous plaques markedly narrowed the mouths of all these arteries. There was also sclerotic involvement of the vessels themselves.

DR COPE: May I ask Dr Allen to comment finally? Our impression, in retrospect, is that the patient had abdominal angina. I have never seen this before. Is that a reasonable diagnosis to entertain here?

DR ALLEN: I think it is. I think that is all right. It has been reported. Cushman and Kilgore,² of San Francisco, reported a case. Dr Jones's explanation is quite reasonable. I think a man who has angina pectoris gets an attack with an increased demand on the heart. Therefore, it seems to be a very reasonable deduction that increased demand on the stomach caused this epigastric pain. But it is a little hard for me to understand why he bled so much from the stomach — a little difficult for me to understand why, in other words, an organ that had insufficient blood supply should not be less likely to bleed than the normal.

DR COPE: He bled after both operations.

DR ALLEN: And before.

DR MALLORY: I think it is important that the coronary vessels were in good shape. There were a few thrombosed plaques, but no significant narrowing. The possibility of cardiac angina with reference of pain to the abdomen is therefore improbable.

DR COPE: In summary, you think it is reasonable to make a diagnosis of prolonged myxedema and atherosclerosis with abdominal angina?

DR MALLORY: That is the best explanation I can give.

CASE 35072

PRESENTATION OF CASE

A nineteen-year-old girl was admitted to the hospital because of severe headache and right orbital swelling.

She had been perfectly well until five days before admission, when she began to have intermittent pain behind both eyes and over the right side of the face and head. The pain became progressively more severe and three days before entry was constant and prevented sleep. At this time tearing of the right eye and dripping of a clear fluid from the right nostril developed. On the following day she developed photophobia in the right eye and vomited three times. Twenty-four hours before admission a short trial with ergotamine tartrate was unsuccessful, but it was thought that she improved following pyribenzamine. There was no fever. However, the pain increased, and that night the right eye began to swell.

Physical examination revealed a well developed and nourished girl who was very drowsy but capable of being aroused and of performing simple tests. The skin was hot. There was marked swelling about both eyes with chemosis, moderate proptosis and supraorbital tenderness, more pronounced on the right side. There was thought to be slight peripapillary edema of the retina. The pupils measured 3 mm in diameter and reacted briskly to light. The external movements of both eyes were "reduced in all directions." There was marked tenderness on the right side, and slight tenderness on the left in the preauricular region and over the right lower jaw. There was a small amount of purulent secretion (less than 1 cc) in each nostril. The middle and inferior turbinates were slightly injected bilaterally. The ears were normal. The neck was rigid, and Kernig's sign was positive. There was dullness over both lung bases posteriorly, breath sounds over the left base were coarse and high pitched on the right. There was tenderness in both upper quadrants of the abdomen and costo-vertebral-angle regions.

The temperature was 103°F, the pulse 80, and the respirations 32.

The urine was normal. The blood hemoglobin was 11.5 gm, the white-cell count was 16,500, with 86 per cent neutrophils. A blood culture was later reported to have grown *Staphylococcus aureus*. A lumbar puncture revealed cloudy spinal fluid under a pressure equivalent to 270 mm of water. Jugular compression on the right produced no change in pressure, on the left it resulted in a good rise. The

cell count was 7000, with 93 per cent neutrophils. A culture was negative.

The patient became more stuporous, and the temperature rose to 104°F. Roentgenograms of the skull and sinuses were normal. She was immediately started on penicillin, streptomycin and intravenous heparin. On the second hospital day the temperature was still elevated, the prothrombin time was 25 seconds (normal, 16 seconds), following which dicumarol therapy was begun. It was noted that the left eye had become as swollen as the right. A second lumbar puncture produced a cloudy, yellow-tinged spinal fluid containing only 481 white cells per cubic millimeter. On the fourth hospital day the prothrombin time was in the neighborhood of 50 seconds (normal, 18 seconds). On the same day the patient had a seizure consisting of clonic movements of the left side of the body, beginning in the face and extending downward, lasting about a minute. Several more seizures occurred but ceased after she had been given dilantin and phenobarbital. Later that day she was semicomatose and found to have a left hemiparesis and hemianopsia. The white-cell count had fallen to 4700, with 80 per cent neutrophils, sulfadiazine administration was stopped. On the next day, however, these last findings had cleared considerably, and although the temperature still fluctuated between 101° and 102°F, she seemed much improved. There had been a progressive reduction in the number of cells in the spinal fluid. The periorbital swelling was considerably reduced, and she was able to open her eyes and look around. On the eighth hospital day, after continued improvement, she complained of chest pain, first on the left and later on the right, accentuated by deep inspiration.

On the following day the white-cell count had risen to 12,300. There was no cough or hemoptysis, and examination of the legs was negative. A roentgenogram of the chest disclosed three small areas of increased density overlying the posterolateral portions of the fifth and seventh ribs on the right side and the ninth rib on the left. Heparin was again started. Twenty-four hours later she appeared acutely ill, pale and moaning. The temperature was 101°F, the pulse 90, and the respirations 25. There were tenderness over the right temple, and tenderness, marked redness and edema of the right eyelid. The right eye was proptosed, and the conjunctiva showed severe chemosis with slight, pink tearing. There was moderate nuchal rigidity, and a positive Kernig's sign, more marked on the left. A lumbar puncture revealed a spinal-fluid pressure equivalent to 180 mm. of water and containing 28 neutrophils per cubic millimeter and a negative smear and culture. On the following day the fundi showed retinal edema, the disk margins were blurred and indistinct, and there was a suggestion of papilledema. The prothrombin time was 24 seconds (normal, 16 seconds).

After another brief period of improvement the patient began to complain of severe pain in the eyes and right ear. She was drowsy most of the time. On the next day she complained of the pain almost constantly and was obviously much weaker. Later in the same day she tried to vomit but could only retch, shortly after which she became unresponsive. The left corneal reflex was absent. There was ankle clonus, moderate on the right and slight on the left, and a positive Babinski on the right. She remained unresponsive and died several hours later, on the thirteenth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. AUGUSTUS S. ROSE. From the history, physical findings and course of this patient we have little question regarding diagnosis. It is obvious that the patient had an infectious process involving the dural sinuses, and in view of the positive blood culture for *Staph aureus* and the early response to therapy we must assume that the infecting organism was *Staph aureus*. There are a number of questions, somewhat unanswered, that require consideration. In the first place, we are told that she was well until five days before admission, eighteen days before death. This is a very rapid termination, particularly in view of the excellent therapy on admission to the hospital, which included sulfadiazine, streptomycin and penicillin. If *Staph aureus* was the only organism, these therapeutic agents should have done—or we would have hoped that they would have done—a better job in arresting the infectious process. The question that bothers me most of all is the source of the infection. The patient was apparently entirely well, no mention being made of a pimple or other local infection on the face or within the nose. The only leads we have are the early symptoms and the finding of pus in the nose. Back in the days before chemotherapy the development of cavernous-sinus thrombosis, which I believe this patient had, was sufficient evidence for immediate consideration of ethmoid sinusitis in the absence of infection on the face. Despite a negative x-ray examination, an acute infection of the ethmoid sinuses may have been the original source of infection. The first symptom recorded was pain behind both eyes, followed very quickly by pain in the face, on one side, and some tenderness and then swelling. Presumably because of the absence of fever, her physician thought of migraine, for which he prescribed ergotamine, and also of a histamine reaction of some sort because of the pyribenzamine. With the entire case before us, the pain behind the eyes makes me think of ethmoiditis. But probably at this time the patient had already begun to develop thrombosis of the cavernous sinus, chiefly on the right. The thrombus was probably infected from the beginning despite the absence of fever. With rapid succession there was swelling of the right eye,

followed in a day by swelling about the other eye. The thrombosis or thrombophlebitis of the cavernous sinus on the right spread via the circular sinus to involve the cavernous sinus on the left. We then have the information of a lumbar puncture done on admission, which showed no rise in spinal-fluid pressure on compression of the right jugular vein, giving evidence that the right lateral sinus had become occluded by the thromboinfectious process. The patient was drowsy, showing considerable involvement and disturbance in function of the brain, and the spinal-fluid pressure was elevated, indicating that venous return from the brain was interfered with. The cell count in the spinal fluid of 7000, predominantly polymorphonuclears, does not of necessity mean a bacterial infection of the surface of the subarachnoid space. But it does point to infection nearby. The two negative cultures of spinal fluid and the absence of bacteria support the concept.

The patient complained of pain in the chest. The House Service evidently thought in terms of emboli because they give us a negative report on the veins of lower extremities, and we also are told that she did not have hemoptysis. X-ray examination, however, showed a shadow in the lung consistent with pulmonary embolus, and I expect that it was an infected embolus without abscess formation. Eighteen days following the onset of the illness is too short for an abscess to form in the lung or in the brain.

The patient was drowsy and had a convulsive seizure on the left side, the opposite side from the occlusion of the lateral sinus. I would reason that the thromboinfective process had extended backward through the sinuses of the dura into the veins of the brain itself and had caused changes within the brain, which may well have been the beginning of an abscess. If she had survived, it is possible that she might have had a circumscribed abscess within the brain, but I doubt if autopsy revealed definite abscess formation.

One other question is, Why did not adequate treatment, which she presumably had, stop the infection? I have to leave that unanswered but assume that this patient's resistance was low, that the virulence of the organism was great and that, by the time treatment was started, infection had already spread not only into the blood stream and cavernous sinuses but also beyond and was an overwhelming infection.

I then summarize by saying that I believe the patient had a primary infection in the ethmoid sinuses from which there developed a thrombophlebitis involving the right cavernous sinus, the right lateral sinus, the left cavernous sinus, the veins of the brain, septicemia, pulmonary infarct and possibly a beginning abscess on the right side of the brain.

DR TRACY B MALLORY Are there any interesting x-ray films?

DR STANLEY M WYMAN I doubt if they are contributory.

DR MALLORY Are there any questions or comments?

DR JAMES B AYER The test for lateral-sinus thrombosis on the right is more accurate than that on the left, so I think Dr Rose's reasoning is probably correct.

CLINICAL DIAGNOSES

Cavernous-sinus thrombosis
Meningitis
Sinusitis
Pulmonary emboli

DR ROSE'S DIAGNOSES

Ethmoiditis
Thrombophlebitis, cavernous sinuses and right lateral sinus
Thrombophlebitis of cerebral veins, with cerebral necrosis
Septicemia
Pulmonary emboli

ANATOMICAL DIAGNOSES

Ethmoiditis and sphenoiditis
Thrombophlebitis of cavernous sinuses and tributary cerebral veins
Venous cerebral infarction
Massive cerebral hemorrhage
Subdural hemorrhage
Meningitis, healed

PATHOLOGICAL DISCUSSION

DR CHARLES S KUBIK The posterior ethmoid cells and sphenoid sinus contained not thick pus but brownish-orange, thick fluid. That presumably was the source of infection along veins of the air sinuses, which empty into the cavernous sinuses. The venous sinuses, with the exception of the cavernous sinuses, were normal. The cavernous sinuses were removed intact with the central portion of the sphenoid bone, sphenoid sinus and posterior ethmoid cells, and on microscopical sections were found to contain purulent exudate and organized thrombi on both sides. There was also infection in the circular sinus, which passes around the pituitary gland and connects the two cavernous sinuses. It is through the circular sinus that infection extends from one side to the other. In the right posterior parietal and temporal regions there was a subdural clot of blood, 0.2 or 0.3 cm in thickness and 3 to 4 cm in diameter. There was blood, apparently fresh, in the subarachnoid space, extending medially to the base of the brain, and a large cerebral hemorrhage, measuring between 4 and 5 cm in diameter, in the right posterior parietal region.

On microscopical examination there was a fair amount of organization of the subdural hemorrhage, indicating that it must have occurred at least a number of days before death. The cerebral and subarachnoid hemorrhage appeared to be recent. In the same region there were thrombosis of cerebral veins that drained into the cavernous sinus and hemorrhagic foci of necrosis of the brain such as occur with arterial and sometimes with venous occlusion. I believe that thrombosis unquestionably extended in retrograde direction from the cavernous sinus to tributary cerebral veins, as suggested by Dr. Rose, and resulted in venous infarction of the brain. Infarcts of the brain, following arterial occlusion, usually are pale with hemorrhagic areas here and there, resulting from innumerable, small, diffuse extravasations and capillary hemorrhages. Venous infarcts are much more likely to be hemorrhagic. Massive hemorrhages are unusual. In this case I believe that the terminal event was a massive hemorrhage, which began as the usual type of hemorrhagic venous infarction. Microscopical examination indicates, I believe, how the large hemorrhage developed. There were some foci of infarction with a few, punctate hemorrhages and other similar foci, with a small, massive hemorrhage in the center. It seems likely that the large hemorrhage began in the same way, or possibly as a number of such small lesions.

There was no grossly visible pus in the orbital tissues — only some punctate, hemorrhagic foci. Microscopical examination of the orbital tissues revealed the ophthalmic veins filled with bland thrombi and surrounded by partly organized hemorrhages and, on the right side, a small, partly walled-off abscess. The optic and oculomotor nerves looked normal.

The spinal subarachnoid spaces contained a few lymphocytes, plasma cells and large mononuclear cells, and there was possibly slight arachnoid

fibrosis — actually surprisingly little reaction, even for recently healed meningitis. The spinal cord itself and the spinal nerves were normal.

There had been indications of considerable clinical improvement for a time after treatment was begun. The mental status improved, proptosis diminished, ocular movements returned, and cells in the spinal fluid dropped from 7000 to 28 per cubic millimeter. The pathological findings also suggest that the natural course of the disease had been greatly modified. Before sulfonamides and antibiotics were available, thrombophlebitis of the cavernous sinus was invariably fatal, at least when it occurred in the severe form observed in this case. At post-mortem examination the cavernous sinuses were distended with pus, and the orbital tissues were honey-combed with abscesses. In this case it is quite possible that recovery would have taken place but for the hemorrhage.

DR. ROSE: Do you believe that the heparin and dicumarol aided the process of intercerebral bleeding?

DR. KUBIK: I think that is quite possible. We have suspected it in cases of subacute bacterial endocarditis, treated with anticoagulants, in which massive cerebral hemorrhage of the brain occurred, apparently in a region of embolic infarction.

DR. JOHN B. STANBURY: Were there any thrombi in the vessels of the neck?

DR. MALLORY: None were found outside the cranial cavity. In the lungs there were multiple, irregular areas of hemorrhage having the appearance of very fresh, slightly atypical infarcts, some of which showed beginning softening in their centers, suggesting that they were septic in character, not as yet broken down into frank abscesses. They were too recent for that.

A PHYSICIAN: How much penicillin was she given?

DR. W. H. TIMBERLAKE: She received amounts varying from 100,000 to 500,000 units every three hours.

EX LIBRIS

Two of the important factors that distinguish man from less elevated animals are the ability to reason and the capacity for speech. A refinement that has enabled each generation of mankind to profit most fully from the experiences of its predecessors has been the recording of ideas and the preservation of these records, whether carved in stone or scratched in tablets of clay, whether traced on papyrus or written in manuscripts or impressed upon the printed page.

Only by consulting its records has man been able to build adequately upon the experiences of the past, of greater importance to his progress than the invention of the wheel has been his establishment of the library, which contributes to his cultural and spiritual as well as to his technical advance.

Some of the brightest chapters in the story of mankind have been illuminated by the development and preservation of literature. Some of the darkest pages in history have been punctuated by the destruction of libraries and the burning of books, from the conflagration at ancient Alexandria to more recent attempts at the destruction of modern culture.

The library as an institution has been one of man's sacred heritages. This applied to the first Sumerian tablet that was laid aside to tell its story four thousand years later, it applies to the most recent text that has been placed on file. This institution is an urgent public charge, from the Library of Congress, supported by an assessment on all the taxpayers, to the smallest village library in existence. And not the least important of these repositories of learning is the Boston Medical Library, which has happily become, as emphasized recently in these pages,* one of the solemn responsibilities of the Massachusetts Medical Society.

In making his contribution to the perpetuation of a library and the continuance of its services, the responsible citizen, whether layman or physician, by no means has in mind what particular benefit he as an individual will derive from it. He can no more calculate the returns on his investment in terms of personal advantage than he can the returns from his contributions to a hospital, the Red Cross, the Salvation Army, the community chest or his church.

The Massachusetts Medical Society has voted an increase in its annual assessment to \$25. Of this sum, \$5.00 from each fellow was allocated to the use of the Boston Medical Library, and has proved to be a most welcome transfusion for this invaluable institution. The discharge of this barest obligation, however, is not enough. There must be in addition an increasing number of thoughtful and responsible physicians willing and eager to pay an additional \$15.00 for fellowship in the Library — not for themselves but to help in preserving the very foundations of their profession.

Nor is this enough. The immediate future of the Library requires the expenditure of \$75,000 for the erection of new stacks, an expansion that is neces-

*Editorial Budget for 1949 *New Eng J Med* 239:155, 1949

sary in order that the institution may continue to rank among the foremost medical libraries of the world. This cannot be done from current income, even if augmented by the accession of new fellows. It must be accomplished as the result of an intellectual renaissance among the physicians of New England, expressed in terms of a material contribution that some modern form of alchemy can convert into the metal of which such equipment is constructed.

MEETING OF THE COUNCIL

THE midwinter meeting of the Council of the Massachusetts Medical Society, held on February 2, would have been of particular significance because of one fact alone. That was the unanimous approval of the action of the Executive Committee in authorizing the Secretary to proceed, as an agent of the American Medical Association, in collecting the assessment that the Association has levied on its members.

Of further significance was the Secretary's report that within two weeks of the mailing of the notice more than 1500 checks have been received from over a quarter of the Society's fellowship, some of the contributions being for sums in excess of that called for. Remarkably few direct refusals to contribute have been received, some of the fellows of the Society have expressed their desire to withhold their contributions until assurance can be given that the American Medical Association will use the fund wisely and constructively.

Under new business the spokesmen for a group of sincere and thoughtful younger fellows of the Society suggested certain constructive proposals that the Society might endorse and strongly recommend to the Association for its adoption. These proposals expressed a belief that the health of the people will be best served by medical care free of Government administration and control, and called attention to the profligate waste and duplication in health programs operated by the Government, as reported by the Hoover Commission. They indicated the belief of their proponents that the manner of expression of policy on the part of the American Medical Association has served to diminish public confidence in that body, and that its

policy should be one of more active and enthusiastic support of constructive proposals for more equitable distribution of medical care. They further suggested endorsement by the Council of the principles for the distribution of medical care that were agreed upon by the Section on Medical Care of the National Health Assembly held in Washington in May, 1948.

These proposals were referred to a joint committee of the Committee on Public Relations and the Committee on Medical Economics.

The reports of the various committees were accepted and their recommendations in general were adopted, the recommendations of the Advisory Subcommittee on Malpractice Insurance regarding listeners at malpractice suits were, however, rejected.

AUREOMYCIN — ANOTHER EFFECTIVE ANTIBIOTIC

THE antibiotics that have proved most active or most promising for clinical use have come either from molds, like penicillin, from spore-forming bacilli, like gramicidin (tyrothricin), subtilin and bacitracin, or from actinomycetes of the genus *Streptomyces*. A concentration of interest in strains of the last genus was stimulated, of course, by the high activity and effectiveness of streptomycin. Another of the recent antibiotics derived from a species of *Streptomyces* was chloromycetin. Some of the unusual properties of this antibiotic — namely, its high degree of effectiveness against rickettsias and against certain of the large viruses as well as the in vitro susceptibility of both gram-negative and gram-positive organisms to that agent — have been referred to in these columns.¹

A new antibiotic, aureomycin, that is derived from a species of soil organism, which has been named *Streptomyces aureofaciens*, has now been shown, on the basis of laboratory evidence and clinical trials, to give promise of being a useful addition in this field. The early reports presented at the New York Academy of Sciences last July² and additional papers that have already appeared^{3, 4} have indicated that aureomycin, like chloromycetin, should prove most useful against infections with all the known rickettsias and with the viruses of the

mphogranuloma-venereum-psittacosis group In addition, aureomycin has been shown to be of considerable, though more limited, therapeutic value in many infections with gram-positive and gram-negative bacteria Like chloromycetin it has the advantage of being effective when used by mouth and is relatively nontoxic

The exact field of usefulness, the toxicity and the limitations of this new antibiotic, however, are still to be worked out

The paper by Finland, Collins and Wells in the present issue of the *Journal* and similar observations by other workers^{13 14} suggest that aureomycin may also be highly effective in the treatment of cases of primary atypical pneumonia, although the authors are quite cautious in the interpretation of their results These findings, however, should stimulate further attempts to isolate and define the etiologic agent in this disease, which has become increasingly prominent as the seriousness of the bacterial pneumonias has been reduced by the use of the available chemotherapeutic and antibiotic agents

— WHAT THY RIGHT HAND DOETH

SOMETHING more than a generation ago universal custom demanded that the American school child write with the right hand, or else A small

army of potential scholars, during those unhappy years, had their slate pencils snatched from their southern paws by irate schoolmarms and were forced thereafter to lead lives of frustration, unlearned in spelling and stuttering in speech Or so it later came to be believed, after the discovery of the specific language disability

This later revelation of recent decades, while it disclosed the injustice that had been done to one group of embryonic citizens, set all to rights for the next The pendulum that had reached the northernmost antipode of its excursion swung back upon its course and drove with equal vigor to the left Since then it has been a foolhardy teacher indeed, or the most ignorant of parents, who would dare disturb the handedness with which heredity, chance, divine providence or a solemn design of inscrutable nature had endowed a child

Why man, outwardly so symmetrical in his anatomic architecture, should exhibit such a stubborn bias in the unilateral development of his manual skills is interestingly discussed by Eustis elsewhere in this issue of the *Journal* No one knows why the preferred hand is the right (a fact discernible on both sides of the equator), and no theory accounts satisfactorily for it Right-handedness becomes most nearly universal as cultural development advances, primitive races show a higher percentage of left-handedness than do cultured races, 5 per cent of civilized adults are left-handed, 20 per cent of whom functioned in the counter-clockwise direction during their kindergarten days

The conclusion may be drawn that environmental pressure is highly important in determining ultimate handedness and that unless inherent preference for the left is particularly strong, an artificially imposed shift to the right may not be the crime against humanity that it has so recently been considered Ambidexterity introduces the really confusing factor It is ambidextrous persons who sometimes know not which way to turn and whose left hands really know not what their right hands do, less certain in their abilities than the companies that rallied to David who "were armed with bows, and could use both the right hand and the left in hurling stones and shooting arrows out of a bow"

sary in order that the institution may continue to rank among the foremost medical libraries of the world. This cannot be done from current income, even if augmented by the accession of new fellows. It must be accomplished as the result of an intellectual renaissance among the physicians of New England, expressed in terms of a material contribution that some modern form of alchemy can convert into the metal of which such equipment is constructed.

MEETING OF THE COUNCIL

THE midwinter meeting of the Council of the Massachusetts Medical Society, held on February 2, would have been of particular significance because of one fact alone. That was the unanimous approval of the action of the Executive Committee in authorizing the Secretary to proceed, as an agent of the American Medical Association, in collecting the assessment that the Association has levied on its members.

Of further significance was the Secretary's report that within two weeks of the mailing of the notice more than 1500 checks have been received from over a quarter of the Society's fellowship, some of the contributions being for sums in excess of that called for. Remarkably few direct refusals to contribute have been received, some of the fellows of the Society have expressed their desire to withhold their contributions until assurance can be given that the American Medical Association will use the fund wisely and constructively.

Under new business the spokesmen for a group of sincere and thoughtful younger fellows of the Society suggested certain constructive proposals that the Society might endorse and strongly recommend to the Association for its adoption. These proposals expressed a belief that the health of the people will be best served by medical care free of Government administration and control, and called attention to the profligate waste and duplication in health programs operated by the Government, as reported by the Hoover Commission. They indicated the belief of their proponents that the manner of expression of policy on the part of the American Medical Association has served to diminish public confidence in that body, and that its

policy should be one of more active and enthusiastic support of constructive proposals for more equitable distribution of medical care. They further suggested endorsement by the Council of the principles for the distribution of medical care that were agreed upon by the Section on Medical Care of the National Health Assembly held in Washington in May, 1948.

These proposals were referred to a joint committee of the Committee on Public Relations and the Committee on Medical Economics.

The reports of the various committees were accepted and their recommendations in general were adopted, the recommendations of the Advisory Subcommittee on Malpractice Insurance regarding listeners at malpractice suits were, however, rejected.

AUREOMYCIN — ANOTHER EFFECTIVE ANTIBIOTIC

THE antibiotics that have proved most active or most promising for clinical use have come either from molds, like penicillin, from spore-forming bacilli, like gramicidin (tyrothricin), subtilin and bacitracin, or from actinomycetes of the genus *Streptomyces*. A concentration of interest in strains of the last genus was stimulated, of course, by the high activity and effectiveness of streptomycin. Another of the recent antibiotics derived from a species of *Streptomyces* was chloromycetin. Some of the unusual properties of this antibiotic — namely, its high degree of effectiveness against rickettsias and against certain of the large viruses as well as the in vitro susceptibility of both gram-negative and gram-positive organisms to that agent — have been referred to in these columns.¹

A new antibiotic, aureomycin, that is derived from a species of soil organism, which has been named *Streptomyces aureofaciens*, has now been shown, on the basis of laboratory evidence and clinical trials, to give promise of being a useful addition in this field. The early reports presented at the New York Academy of Sciences last July² and additional papers that have already appeared³⁻¹² have indicated that aureomycin, like chloromycetin, should prove most useful against infections with all the known rickettsias and with the viruses of the

lymphogranuloma-venereum-psittacosis group. In addition, aureomycin has been shown to be of considerable, though more limited, therapeutic value in many infections with gram-positive and gram-negative bacteria. Like chloromycetin it has the advantage of being effective when used by mouth and is relatively nontoxic.

The exact field of usefulness, the toxicity and the indications of this new antibiotic, however, are still to be worked out.

The paper by Finland, Collins and Wells in the present issue of the *Journal* and similar observations of other workers^{13, 14} suggest that aureomycin may also be highly effective in the treatment of cases of primary atypical pneumonia, although the authors are quite cautious in the interpretation of their results. These findings, however, should stimulate further attempts to isolate and define the etiologic agent in this disease, which has become increasingly prominent as the seriousness of the bacterial pneumonias has been reduced by the use of the available chemotherapeutic and antibiotic agents.

— WHAT THY RIGHT HAND DOETH —

SOMETHING more than a generation ago universal custom demanded that the American school child write with the right hand, or else. A small

army of potential scholars, during those unhappy years, had their slate pencils snatched from their southern paws by irate schoolmarms and were forced thereafter to lead lives of frustration, unlearned in spelling and stuttering in speech. Or so it later came to be believed after the discovery of the specific language disability.

This later revelation of recent decades, while it disclosed the injustice that had been done to one group of embryonic citizens, set all to rights for the next. The pendulum that had reached the northernmost antipode of its excursion swung back upon its course and drove with equal vigor to the left. Since then it has been a foolhardy teacher indeed, or the most ignorant of parents, who would dare disturb the handedness with which heredity, chance, divine providence or a solemn design of inscrutable nature had endowed a child.

Why man, outwardly so symmetrical in his anatomic architecture, should exhibit such a stubborn bias in the unilateral development of his manual skills is interestingly discussed by Eustis elsewhere in this issue of the *Journal*. No one knows why the preferred hand is the right (a fact discernible on both sides of the equator), and no theory accounts satisfactorily for it. Right-handedness becomes most nearly universal as cultural development advances: primitive races show a higher percentage of left-handedness than do cultured races, 5 per cent of civilized adults are left-handed, 20 per cent of whom functioned in the counter-clockwise direction during their kindergarten days.

The conclusion may be drawn that environmental pressure is highly important in determining ultimate handedness and that, unless inherent preference for the left is particularly strong, an artificially imposed shift to the right may not be the crime against humanity that it has so recently been considered. Ambidexterity introduces the really confusing factor. It is ambidextrous persons who sometimes know not which way to turn and whose left hands really know not what their right hands do, less certain in their abilities than the companies that rallied to David who "were armed with bows, and could use both the right hand and the left in hurling stones and shooting arrows out of a bow."

MASSACHUSETTS HEALTH CONFERENCE, INC

AN outstandingly progressive step toward the better distribution of medical care in Massachusetts was taken on November 28, 1948. On that date representatives of fifty or more "consumer" and "distribution" groups met together and organized the Massachusetts Health Conference, Inc.

First fruits of this organization consist of the Conference about to take place, on February 19 and 20, at the Hotel Statler, in Boston. Honorary chairman of the Conference is His Excellency, Governor Paul A. Dever, the chairman is Mr. Philip R. Mather, president of the National Health Conference. The president is Dr. John F. Conlin, director of medical information and education of the Massachusetts Medical Society, the vice-president is Mr. John J. Devlin, of the American Federation of Labor, and the secretary-treasurer is Mr. Louis T. Maloney, executive secretary of the Massachusetts Dental Society. The first Conference objective is "Means of Improving Health in Massachusetts during the Next Five Years."

It is a notable thing when members of diverse groups including both distributors and consumers sit down together to discuss their mutual problems, and a refreshing acknowledgment of the fact that most worthwhile objectives need to be viewed from various vantage points.

MASSACHUSETTS MEDICAL SOCIETY

TREASURER'S OFFICE

All members should be reminded that the proportion of the refund returned to each district society is based on the number of dues paid by March 1 in that district, and also that the names of members who have not paid their dues by March 1 are automatically removed from the mailing list of the *Journal* until such dues are paid. This year \$8000 is being returned to the district societies.

ELIOT HUBBARD, JR., *Treasurer*

BOSTON MEDICAL LIBRARY

Thanks to the loyal support of the members of the Massachusetts Medical Society the Boston Medical Library has been able to render greater service than ever before. During the past year 42,638 books and periodicals were made use of whereas the previous highest circulation had been

38,266 in any one year. Of considerable interest is the fact that over 9000 users of the Library were neither fellows, Society members nor members. This is the kind of service that should be rendered and rendered gladly. It represents the same type of service rendered by a free public library, which must be paid for out of taxes. The added income received from the Massachusetts Medical Society members enables the Library to furnish this service.

The personnel of the Library has been increased and 1000 more periodical volumes have been prepared and bound than during the previous year. The library has increased in size by over 2500 volumes and 4000 pamphlets. It is still far from its goal, but it is on its way.

The great need now is to obtain enough money to complete the stacks so that valuable volume will be more readily available. This will cost approximately \$75,000.

Next year the Boston Medical Library celebrates its seventy-fifth anniversary, and it is hoped that it may be celebrated by dedicating the new stacks. The members of the Massachusetts Medical Society can rightly take pride in their contribution to help support and carry on the work of this great and valuable library.

WALTER G. PHIPPEN, *President*

CORRESPONDENCE

COMMITTEE FOR THE NATION'S HEALTH

To the Editor: A bill has been introduced into the 81st Congress to develop a national health program. With the President strongly in its favor and the Congress composed as it is, there is a reasonable chance that such legislation will be enacted into law. It is important, therefore, that the medical profession and others to whom Congress will turn for advice be so informed on the subject that clear thinking will result. Unfortunately, appreciable misinformation regarding the subject has been broadcast throughout the country. A recent example is the inaugural address by Dr. William B. Rawls on assuming the presidency of the Medical Society of the County of New York. This address, which received publicity in the lay and medical press, contained many inaccurate statements and misleading innuendoes, and specifically mentioned me and the Committee for the Nation's Health, of which I have the honor to be chairman. I have corresponded with Dr. Rawls in the hope that he would be willing to correct these inaccuracies, but we have been unable to come to an agreement on the facts. We have left our correspondence with the understanding that I would present my point of view for the benefit of the physicians and laymen. Naturally, I prefer to present the subject through the medical press, and therefore, I hope you will be willing to publish this letter in the *Journal*, which is the medium in which I should like to have any communication from me published.

In his address Dr. Rawls says, "One of the major weaknesses of Compulsory Health Insurance is that it makes no provision whatsoever for the care of those people who are not able to pay their own medical expenses." In all the proposed legislation so far supported by the Committee for the Nation's Health the medically indigent — namely, those provided for in part by Government or charity — will cease to be indigent and under the plan become the private patients of their own physicians. Furthermore, provision is made under the plans so that local communities can insure the really indigent for whom they must accept responsibility.

The address presents as evidence for Dr. Rawls's point of view the study of the status of medical care in the United States by the Brookings Institute without pointing out that

two experts in the field have filed an unchallenged criticism of this report with the Sub-committee on Health of the Senate Committee on Labor and Public Welfare

The address says that compulsory health insurance will result in the socialization of medicine. At the present time we do not have compulsory health insurance, but we do have a great deal of socialized medicine as defined by General Paul R. Hawley, chief executive officer of the Blue Cross and Blue Shield Commission, who says, "Socialized medicine is medical care supported in whole or in large part by tax money and regulated by the government." Among good examples are the United States Public Health Service, the Veterans Administration, state universities and many tax-supported hospitals.

Dr Rawls calls attention to the statement of Bernard M. Baruch, regarding the relation of doctors to Government "I oppose socialization here. It leads ultimately to the police state, degradation of the individual and lessened well-being." No mention was made that in the same speech Mr Baruch said, "Your organizations have been particularly active in pressing voluntary health insurance. But I would not be frank — nor friendly — if I did not add what you know. It is not good enough." Mr Baruch then went on in the same speech to propose compulsory health insurance. He declared "Nationally, the program might well be administered by a body of doctors and non-doctors to keep medical care as free from politics as possible." This program, he pointed out, "can be devised, adequately safeguarded, without involving what has been termed 'socialized medicine'."

Without specific reference the address stated that recent public-opinion polls have shown that compulsory health insurance is not the desire of the people. The following specific references on this subject are offered

A statement by the National Opinion Research Center, University of Denver, in 1944, that "85 per cent thought social security should include doctor and hospital care."

A 1946 poll by the California Medical Association showed that 50 per cent of California residents favor some Government medical program.

A poll in 1946 in New York State under the direction of a Commission on Medical Care appointed by Governor Thomas E. Dewey, showed that 84 per cent of New York State residents want health insurance.

Although the address did not specifically say that everyone who is in favor of what is loosely called socialized medicine is a Communist, appreciable space was given to the innuendo that those supporting compulsory health insurance are dominated by Communism. A survey of the individuals and groups supporting the compulsory health insurance program should make clear to any fair-minded person the absurdity of this innuendo. President Harry S. Truman, Jonathan Daniels, Russell Davenport, William Green, Bishop Francis J. McConnell, Philip Murray, Bishop G. Bromley Oxnam, Mrs. Franklin D. Roosevelt, David Sarnoff, Gerard Swope, Dr. Thomas Addis, Barry Bingham, Dr. Ernst P. Boas, Morris Llewellyn Cooke, John J. Corson, Mrs. Gardner Cowles, Michael M. Davis, Albert W. Dent, Abe Fortas, Mary Dublin Keyserling, Carl C. Lang, Mrs. Albert D. Lasker, Dr. John V. Lawrence, Dorothy Norman, Emil Rieve, Anna M. Rosenberg, V. Henry Rothschild, Second, R. M. Walls, D.D.S., and Matthew Woll. The program is also supported by six United States Senators, four of whom are members of a church that is irreconcilably opposed to Communism. Seventeen national organizations with memberships totaling some 18,000,000 persons endorsed nation-wide compulsory health insurance last spring at the National Health Assembly.

The address of Dr. Rawls declared that the conclusions of the Congressional Sub-committee on Publicity and Propaganda, often spoken of as the Harness Committee, have never been seriously denied. This committee claims that federal employees spent public funds improperly in furthering the cause of compulsory health insurance. The address did not mention that these charges have been referred to the Attorney General of the United States, and that he has up to the present time not seen fit to act upon them, which at least suggests that the charges of the Harness Committee cannot be substantiated.

The Tolvo Mission was cited as another instance of an attempt of Government employees to promote socialized medicine, the following quotation of the Harness Com-

mittee's Report being beld as an example "The real purpose of this Mission was to lay the groundwork for a system of socialized medicine in Japan and the scheme for such a Mission originated in the Division of Research and Statistics in the Social Security Board in Washington and nowhere else." Actually, it had been clearly demonstrated to this Senate Subcommittee that the Administration's health experts went to Japan at the explicit request of General MacArthur and his staff. In an official communication to Representative Harness, chairman of the committee that spread the false charge, MacArthur made clear that the request originated in his office, and that the purpose of the mission was to help reconstruct the national health insurance system, which had been instituted in that country by the Japanese in 1926.

The address said that Michael M. Davis, one of the principal founders and the most active member of the Committee for the Nation's Health was formerly an employee of the Social Security Administration. To correct this I call attention to the fact that Dr. Davis has never been a federal employee. Like many distinguished experts he has been asked by the Government to assist as a consultant from time to time. There is pay at \$25.00 per day for a consultant. A consultant, however, is not an employee.

The address called attention to the fact that the Committee for the Nation's Health is registered with the Government as paid lobbyists. This is correct. If the implication in the address is that such activity is improper, it is only fair to call attention to the fact that the American Medical Association maintains a registered lobbyist in Washington and that the National Physicians Committee, closely allied to and approved by the American Medical Association, is also so registered, and further that its annual expenditures are ten times that of the Committee for the Nation's Health.

The address quotes from a report of the Canadian Royal Commission about the German plan of "political medicine" since 1884 as follows "You will note the ever-expanding medical bureaucracy with its ever swelling tide of taxes and appropriations. After this process had been going on for fifty years, the whole arrangement was taken over lock, stock and barrel by Adolf Hitler, and the government's medical program was looked upon by many as one of the greatest props of the totalitarian state." Just what implication is meant from this quotation is not clear, but the address failed to mention that this same commission recommended Nation-wide Compulsory Health Insurance for Canada and that this recommendation was approved by the Canadian Medical Association. There are no obscure implications in these last two statements.

My hope is that the above corrections regarding fact and misleading innuendoes will permit members of a scientific profession to reach a decision about what type of national health program will be best.

FAVORING THE ASSESSMENT

To the Editor: To those who object to the \$25 assessment that we may have medical freedom, the answer can be given that indirectly they are paying Mr. Ewing far more per capita to secure their enslavement.

The assessment is a small amount, and all should cheerfully contribute that much and more, if able, in order to maintain our medical standards as they are and not to have directives from Washington.

JUSTUS G. HANSON, M.D.

218 Elm Street
Northampton, Massachusetts

BOOK REVIEW

Handbook for the Medical Secretary. By Miriam Bredow. Second edition. 8°, cloth, 389 pp., with 36 illustrations. New York: McGraw-Hill Book Company, Incorporated, 1948. \$2.75.

This handbook, first published in 1943, has been revised, and the text brought up to date. A new section on secretarial duties in relation to veteran patients has been added to this edition. The whole field of office and patient management is covered, and there are special chapters on the preparation of manuscripts, the doctor and the law and the dental secretary.

The *World List of Scientific Periodicals*, which is not generally used to any great extent in the United States, is employed by the author instead of the abbreviations of the *Quarterly Cumulative Index Medicus* and the *Index Catalogue*, which are commonly used in this country. In the chapter on medical terminology there is a large vocabulary, comprising over 2000 medical terms, arranged by sixteen subjects. This list would have been more useful if all the terms had been arranged in one alphabet. The volume is well published. The work is intended as a student's textbook in teaching institutions, presenting courses for medical secretaries, office assistants and laboratory technicians. The book should prove useful also to all medical secretaries and should be in all medical libraries as a reference text.

NOTICES

NEW YORK STATE FELLOWSHIPS FOR TRAINING IN PUBLIC HEALTH

Fellowships to train physicians to qualify for public-health positions in New York State are available. The fellowships carry a stipend of \$3,600 per year and are for one year or more, depending upon the training required. The types of training and qualifications are as follows: health officer, consisting of six or more months' supervised experience in a selected county or district health department followed by one academic year at an approved school of public health, leading to a degree of master of public health (applicant must be a citizen of the United States, graduate of an approved medical college, have an internship of one year in a hospital approved for such internship, be licensed or eligible to take the examination for license to practice in New York State and preferably should be no more than thirty-five years of age, although the age requirement may be waived), tuberculosis physician, consisting of three months in a tuberculosis hospital, nine months' supervised experience in tuberculosis clinics and two months' general public-health training in a selected district or county health department, with provision, if desired, for academic training, leading to a master of public health degree (applicant for this training must be a citizen of the United States, graduate of an approved medical college, have an internship of one year in a hospital approved for such internship, be licensed or eligible to take the examination for license to practice medicine in New York State and preferably should be no more than thirty-five years of age, although the age requirement may be waived), clinical consultant in venereal disease, in pediatrics, in obstetrics or in the administration of a specialized program such as cancer control requiring training in the clinical specialty concerned, as well as in general public health, for not more than two years to qualify for these specialty positions (applicant for this training must be a citizen of the United States, graduate of an approved medical college, licensed or eligible to take the examination for license to practice medicine in New York State and must have some experience in the clinical field for which he will be further trained), and laboratory director, consisting of one year of planned instruction in the New York State Health Department laboratory (applicant must be a citizen of the United States, licensed or eligible to take the examination for a license to practice medicine in New York State and must have had at least one year's laboratory training and experience).

Applications are invited by the New York State Department of Health. Further information and application forms may be obtained from Dr. Franklyn B. Amos, director of the Office of Professional Training, New York State Health Department, Governor Alfred E. Smith State Office Building, Albany 1, New York.

NEW ENGLAND CENTER HOSPITAL

The corporate name of the charitable corporation that operates the Joseph H. Pratt Diagnostic Hospital and the Ziskind Research Laboratories and will operate the new surgical hospital has been changed to New England Center Hospital. The individual units will continue to use their old names, but in referring to them as a group and also for certain formal purposes the new name will be used.

This is a change of name only and has no other significance or effect.

SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, May 5, at 4 p.m.

CORNELL MEDICAL ALUMNI ASSOCIATION

The alumni day activities of Cornell University Medical College Alumni Association will be held on Thursday, March 24, at the College. The program will include lectures, a surgical program, research demonstrations, the annual meeting of the Association and an evening entertainment at the Waldorf-Astoria.

All Cornell medical graduates are urged to attend.

AMERICAN COLLEGE OF ALLERGISTS

The annual meeting of the American College of Allergists will be held at the Palmer House, Chicago, from April 14 to 17. The program will include a motion picture in color entitled "Bronchoscopy," a symposium entitled "Molds: Fungi in the Etiology of Respiratory Allergic Diseases" and a discussion "Cottonseed Protein vs. Cottonseed Oil Sensitivity," as well as papers on other aspects of allergy and a panel discussion on "Pediatric Allergy." There will be more than twenty scientific and forty technical exhibits.

Members of the College and their wives, as well as non-members, are invited. Registration, free of charge, is required. Those attending the meeting are requested to make their own hotel reservations directly with the reservation manager, Palmer House, Chicago 90, Illinois.

AMERICAN ACADEMY OF GENERAL PRACTICE

The first annual scientific assembly of the American Academy of General Practice will be held at the Netherland Plaza Hotel, Cincinnati, March 7, 8 and 9. The following doctors will speak: Walter C. Alvarez, Rochester, M. Edward Davis, Chicago, Paul A. Davis, Akron, John E. Dees, Durham, Charles A. Doan, Columbus, Joseph A. Freiberg, Cincinnati, Lowell S. Goin, Los Angeles, Francis C. Grant, Philadelphia, Tinsley R. Harrison, Dallas, Robert A. Kehoe, Cincinnati, John A. Kolmer, Philadelphia, Karl A. Meyer, Chicago, Norman F. Miller, Ann Arbor, Francis D. Murphy, Milwaukee, Franklin D. Murphy, Kansas City, Walter J. Reich, Chicago, Howard A. Rusk, New York City, Tom D. Spies, Birmingham, Philip Thorek, Chicago, and Herman G. Weiskotten, Syracuse.

Scientific sessions will be held on all three days of the meeting. The program is a broad one, selected by general practitioners for general practitioners, and featuring topics of down-to-earth value to the man in general practice.

The Academy extends the invitation to attend to all members of the American Medical Association.

For reservations application should be made to Subcommittee on Hotels, American Academy of General Practice, 910 Dixie Terminal Building, Cincinnati 2, Ohio.

GASTRIC ULCER*

A Study of the Massachusetts General Hospital Cases During the Ten-Year Period 1938-1947

CLAUDE E. WELCH, M.D.,† AND ARTHUR W. ALLEN, M.D.‡

BOSTON

GASTRIC ulcer has been recognized as a clinical entity for many years. However, it is so closely related to duodenal ulcer on the one hand and gastric cancer on the other that various authorities tend to emphasize either the benign or the malignant aspect to the exclusion of the other. Obviously, in the former case, gastric ulcer would become a minor subdivision of peptic ulcer, and the surgical treatment would consist of control of the complications. In the latter, gastric ulcers are regarded as actually malignant, or so similar to gastric cancer that all should be operated on and the only remaining problems are technical details involved in gastric resection.

Therefore it has seemed important to re-examine the management of patients with gastric ulcer on the basis of the cases studied in the Massachusetts General Hospital during the ten-year period 1938-1947. Additional knowledge of several aspects of the problem has been gained during this time. The most important include a study of the ulcer-cancer relation, the treatment of the most common complication of gastric ulcer (hemorrhage) and the development of a satisfactory operative technic, especially for ulcers about the cardia.

GENERAL CONSIDERATIONS

The diagnosis of gastric ulcer was made in a total of 512 patients in this period (Table 1). Acute perforations have been excluded, since later study has proved that many of them actually are due to duodenal rather than gastric ulcer. The average age at admission to the hospital was fifty-five years, the distribution according to age groups being as follows: ten to nineteen, 0.6 per cent, twenty to twenty-nine, 2.8 per cent, thirty to thirty-nine, 8.4 per cent, forty to forty-nine, 20.4 per cent, fifty to fifty-nine, 32.4 per cent, sixty to sixty-nine, 22.8 per cent, seventy to seventy-nine, 12.2 per cent,

and eighty to eighty-nine, 0.4 per cent. About an eighth of the patients appeared before forty years of age, and an eighth after seventy. Since the duration of symptoms before admission averaged approximately five years, the average age at onset was fifty. Gastric ulcer therefore is essentially a disease of the older age groups, in contrast to duo-

denal ulcer, in which the average age at onset of symptoms is about thirty.

The disease is almost exactly three times as common in males (74 per cent) as it is in females (26 per cent).

PROBLEM OF ULCER AND CANCER

Early studies by Holmes and Hampton¹ indicated that all prepyloric ulcerations were malignant, and Sproull² proved the extreme rarity of benign ulcer on the greater curvature. In recent years, improved x-ray technics and the use of the gastroscope have demonstrated many ulcers that would have been overlooked twenty years ago. Coincidentally, there has been a great increase in the number of gastric resection so that histologic confirmation of the clinical diagnosis has been possible much more frequently than it was heretofore.

It is clear that the greater the number of resections the more accurate will be the estimated error in the diagnosis of cancer. For in some cases treated medically as benign ulcer the patients will certainly die of cancer of the stomach, but only rarely can these patients be followed long or closely

The *World List of Scientific Periodicals*, which is not generally used to any great extent in the United States, is employed by the author instead of the abbreviations of the *Quarterly Cumulative Index Medicus* and the *Index Catalogue*, which are commonly used in this country. In the chapter on medical terminology there is a large vocabulary, comprising over 2000 medical terms, arranged by sixteen subjects. This list would have been more useful if all the terms had been arranged in one alphabet. The volume is well published. The work is intended as a student's textbook in teaching institutions, presenting courses for medical secretaries, office assistants and laboratory technicians. The book should prove useful also to all medical secretaries and should be in all medical libraries as a reference text.

NOTICES

NEW YORK STATE FELLOWSHIPS FOR TRAINING IN PUBLIC HEALTH

Fellowships to train physicians to qualify for public-health positions in New York State are available. The fellowships carry a stipend of \$3,600 per year and are for one year or more, depending upon the training required. The types of training and qualifications are as follows: health officer, consisting of six or more months' supervised experience in a selected county or district health department followed by one academic year at an approved school of public health, leading to a degree of master of public health (applicant must be a citizen of the United States, graduate of an approved medical college, have an internship of one year in a hospital approved for such internship, be licensed or eligible to take the examination for license to practice in New York State and preferably should be no more than thirty-five years of age, although the age requirement may be waived), tuberculosis physician, consisting of three months in a tuberculosis hospital, nine months' supervised experience in tuberculosis clinics and two months' general public-health training in a selected district or county health department, with provision, if desired, for academic training, leading to a master of public health degree (applicant for this training must be a citizen of the United States, graduate of an approved medical college, have an internship of one year in a hospital approved for such internship, be licensed or eligible to take the examination for license to practice medicine in New York State and preferably should be no more than thirty-five years of age, although the age requirement may be waived), clinical consultant in venereal disease, in pediatrics, in obstetrics or in the administration of a specialized program such as cancer control requiring training in the clinical specialty concerned, as well as in general public health, for not more than two years to qualify for these specialty positions (applicant for this training must be a citizen of the United States, graduate of an approved medical college, licensed or eligible to take the examination for license to practice medicine in New York State and must have some experience in the clinical field for which he will be further trained), and laboratory director, consisting of one year of planned instruction in the New York State Health Department laboratory (applicant must be a citizen of the United States, licensed or eligible to take the examination for a license to practice medicine in New York State and must have had at least one year's laboratory training and experience).

Applications are invited by the New York State Department of Health. Further information and application forms may be obtained from Dr. Franklyn B. Amos, director of the Office of Professional Training, New York State Health Department, Governor Alfred E. Smith State Office Building, Albany 1, New York.

NEW ENGLAND CENTER HOSPITAL

The corporate name of the charitable corporation that operates the Joseph H. Pratt Diagnostic Hospital and the Ziskind Research Laboratories and will operate the new surgical hospital has been changed to New England Center Hospital. The individual units will continue to use their old names, but in referring to them as a group and also for certain formal purposes the new name will be used.

This is a change of name only and has no other significance or effect.

SUFFOLK CENSORS' MEETING

The censors of the Suffolk District Medical Society will meet for the examination of candidates at the Boston Medical Library, 8 Fenway, on Thursday, May 5, at 4 p. m.

CORNELL MEDICAL ALUMNI ASSOCIATION

The alumni day activities of Cornell University Medical College Alumni Association will be held on Thursday, March 24, at the College. The program will include lectures, a surgical program, research demonstrations, the annual meeting of the Association and an evening entertainment at the Waldorf-Astoria.

All Cornell medical graduates are urged to attend.

AMERICAN COLLEGE OF ALLERGISTS

The annual meeting of the American College of Allergists will be held at the Palmer House, Chicago, from April 14 to 17. The program will include a motion picture in color entitled "Bronchoscropy," a symposium entitled "Mold Fungi in the Etiology of Respiratory Allergic Diseases" and a discussion "Cottonseed Protein vs. Cottonseed Oil Sensitivity," as well as papers on other aspects of allergy and a panel discussion on "Pediatric Allergy." There will be more than twenty scientific and forty technical exhibits.

Members of the College and their wives, as well as non-members, are invited. Registration, free of charge, is required. Those attending the meeting are requested to make their own hotel reservations directly with the reservations manager, Palmer House, Chicago 90, Illinois.

AMERICAN ACADEMY OF GENERAL PRACTICE

The first annual scientific assembly of the American Academy of General Practice will be held at the Netherland Plaza Hotel, Cincinnati, March 7, 8 and 9. The following doctors will speak: Walter C. Alvarez, Rochester, M. Edward Davis, Chicago, Paul A. Davis, Akron, John E. Dees, Durham, Charles A. Doan, Columbus, Joseph A. Freiberg, Cincinnati, Lowell S. Goin, Los Angeles, Francis C. Grant, Philadelphia, Tinsley R. Harrison, Dallas, Robert A. Keboe, Cincinnati, John A. Kolmer, Philadelphia, Karl A. Meyer, Chicago, Norman F. Miller, Ann Arbor, Francis D. Murphy, Milwaukee, Franklin D. Murphy, Kansas City, Walter J. Speis, Chicago, Howard A. Rusk, New York City, Tom D. Rich, Birmingham, Philip Thorek, Chicago, and Herman G. Weiskotten, Syracuse.

Scientific sessions will be held on all three days of the meeting. The program is a broad one, selected by general practitioners for general practitioners, and featuring topics of down-to-earth value to the man in general practice.

The Academy extends the invitation to attend to all members of the American Medical Association.

For reservations application should be made to Subcommittee on Hotels, American Academy of General Practice, 910 Dixie Terminal Building, Cincinnati 2, Ohio.

eugenol will increase the accuracy of this test even more

The presence of an accompanying active duodenal ulcer is strong evidence that the gastric ulcer is benign. Figures from the Mayo Clinic⁷ indicate that 0.1 per cent of patients with duodenal ulcer will have carcinoma of the stomach, and 1 per cent of those with duodenal ulcer will have an associated benign ulcer of the stomach.

The presence of multiple gastric ulcers also suggests that the lesions are benign. However, all combinations of ulcer and cancer are seen occasionally, with multiple benign ulcers, associated benign duodenal or gastric ulcer and distinct carcinoma, and multiple ulcerating carcinomas.

In this series multiple gastric ulcers were found in 8 per cent of the patients. Four distinct ulcers were present in one case. Four per cent of the patients had associated gastric and duodenal ulcers.

COMPLICATIONS OF GASTRIC ULCERATION

Incidence

Massive hemorrhage appears to be slightly less frequent with malignant ulcers than with benign since it occurred in only 6 per cent of the cases of ulcer-cancer, compared with benign ulcer, in which the incidence was 9 per cent. On the other hand, pyloric obstruction was much more common, occurring in 19 per cent of the ulcer-cancer group, and in only 1.2 per cent of the benign cases. Perforations, nearly always walled off by adjacent viscera, occur with about equal frequency in both groups.

RATE OF HEALING

The rate of healing of a gastric ulcer is still regarded as the most reliable differential feature between benign ulcer and cancer. Even this fact is not absolute, since in this series two ulcers apparently healed entirely under hospital care but recurred shortly thereafter, and resection proved them to be carcinoma. These rare cases, however, are exceptions to the rule that only benign ulcers tend to heal rapidly. It is also true that some ulcers that prove to be benign fail to heal in a period of months, especially in the older age groups.

This method of differentiation has been applied in a large number of cases in this hospital. In patients that have done well under medical management, significant improvement is usually apparent after a three-week interval. Although complete healing is rare at this time, it occasionally occurs. The average ulcer has healed completely in two months, although at times as long a period as four months is required before the lesion entirely disappears. Consequently, the decision to abandon or continue medical treatment must usually be made a month after the patient is admitted to the hospital. In individual cases, especially in older patients, it may be necessary to wait longer for heal-

ing. Such patients must be followed closely, however, until healing is complete.

The proponents of immediate operation for all gastric ulcers⁹ maintain that this delay is very dangerous from the point of view of spread of misdiagnosed cancers during the interval. On the other hand, it may be pointed out that since the average duration of symptoms before the patient arrives in the hospital is one and a half years, the relatively short extra delay should impose little hazard.

This point obviously cannot be proved by statistics. But it is of interest that of the patients who were believed to have benign ulcer but who were operated on with a delay of less than one month after reaching the hospital, 40 per cent are living and well five years later, of those who were followed for six months or more and then were found to have cancer at operation, all are dead of the disease.

In summary, it is certain that the differential diagnosis of ulcer and cancer cannot be made by present technics in about 10 per cent of the cases. From the point of view of cancer control all gastric ulcers should therefore be operated on at once. However, with care, it is possible to select a small group that can be managed medically if they are closely followed. Following these principles, 97 per cent of the patients who had resections for gastric ulcer were treated correctly. It is of interest that the 9 patients in this series who were followed an inordinate period before resection (the errors in judgment) were exactly equal in number to the deaths after resection.

Types

The complications of gastric ulcer are the same as those of duodenal ulcer, but vary in certain respects. *Perforation* of a chronic gastric ulcer along the lesser curvature is nearly always so gradual that the liver or pancreas walls off the lesion so closely that a general peritonitis does not occur. On the other hand, perforations of so-called acute gastric ulcers close to the pylorus are nearly all duodenal perforations. These free perforations into the peritoneal cavity follow the same course, whether they originate on the duodenal or gastric side of the pyloric vein. *Obstruction* may occur either at the pylorus or, rarely, at an hourglass constriction. In this series, no cases of the latter type were observed. It should also be noted that though reflex vomiting is common with gastric ulcer, pyloric obstruction significant enough to be noted by x-ray examination is much more likely to be due to duodenal ulcer or gastric cancer than it is to gastric ulcer. The demonstration of a gastric ulcer by x-ray study combined with the clinical findings of partial or total pyloric obstruction is therefore an absolute indication for operation. *Hemorrhage* is by far the most common and important complication, occurring as massive bleeding in almost exactly

enough for a final diagnosis to be made. Consequently, the cases reported below, in which an aggressive surgical attack has led to resections in nearly 60 per cent of the entire series, are especially significant.

In this group, 34 of the 512 cases originally diagnosed as gastric ulcer were finally found to be cancer. This was an over-all diagnostic error of 6.6 per cent. Of the patients who had resections and therefore final diagnoses, 32 out of 295, or 10.8 per cent, were proved to have cancer (Table 2).

TABLE 2 *Error in Diagnosis of Cancer*

GROUP	ORIGINAL DIAGNOSIS OF BENIGN ULCER	FINAL DIAGNOSIS OF CANCER	ERROR IN DIAGNOSIS %
All cases	512	34	6.6
Cases with resections	295	32	10.8

The absolute diagnostic error therefore now lies between 6.6 and 10.8 per cent, and we believe that it is very near to 10 per cent. Since the error in a previous study was at least 14 per cent,³ there has been definite improvement during the past decade. It is pertinent to inquire why this change has occurred and to discuss briefly the differential diagnosis of benign ulcer and cancer.

In the first place, it is well to emphasize that the clinician is almost wholly at the mercy of the radiologist and gastroscopist so far as diagnosis is concerned. To illustrate this point, it may be noted as shown previously³ that 65 per cent of the lesions in the prepyloric area that demonstrate ulceration are cancer. But, at present, with the use of spot films, when a highly competent radiologist calls an ulcer in this area benign, his diagnostic error will be approximately 10 per cent.

No one appreciates his limitations in this respect more than the radiologist, who realizes his inability to make a microscopical diagnosis. It has therefore become the custom to report this group of ulcers as "gastric ulcer, grossly benign." The gastroscopist is limited in the same fashion. To their interpretations, data of less diagnostic importance may be added, including the duration of symptoms, the location of the lesion, the size of the ulcer, the gastric analysis, the cytologic smear of the gastric contents, the presence or absence of accompanying ulcers or complications, and the rate of healing under medical therapy to help distinguish ulcers that are microscopically benign from ulcers that are microscopically malignant ("ulcer-cancer").

AGE AND DURATION OF SYMPTOMS

A short gastric history in a patient fifty years of age or over is highly suggestive of cancer. The average duration of symptoms in patients with "ulcer-cancer" before entry to the hospital is one

and a half years, compared with a duration of five years in patients with benign ulcers. The duration of symptoms with "ulcer-cancer" varied from less than a month to ten years. The ages varied from twenty-six to seventy-seven years for ulcer-cancer, whereas the average age of the entire group was fifty-one years.

LOCATION OF THE LESION

Increasing accuracy in x-ray technic has resulted in the differentiation of many of the benign ulcers and ulcerating carcinomas, especially in the prepyloric area. At present the diagnosis of benign ulcer in the pyloric and prepyloric areas is nearly as accurate as and the error in diagnosis of cancer not much higher than that of lesions on the mid-lesser curvature. Schatzki and Eyster⁴ have found, in an independent review of the same cases, that the radiologic diagnostic error of gastric lesions throughout the stomach is highest in the region of the cardia, less in the prepyloric area and least along the mid-lesser curvature. It is of interest to note that in the period from 1938 to 1947, 6 benign ulcers of the greater curvature were resected.

SIZE OF THE ULCER

Although previous studies have shown that the incidence of cancer increases with the size of the ulceration, very little attention should be paid to this feature in the individual case. It is apparent that early operation will increase the number of resected small ulcerating carcinomas. In this series, the average diameter of the malignant ulcer was 1.8 cm., and only 1 was over 2.5 cm. The benign ulcers that were resected averaged 1.6 cm., and the largest benign ulcer was 7.0 cm. in diameter.

GASTRIC ANALYSIS

The presence of free hydrochloric acid is of no significance although its absence after the use of histamine is strongly suggestive of cancer. Free hydrochloric acid is found in approximately 90 per cent of the patients with benign ulcer and of those with ulcer-cancer. About 40 per cent of carcinomas of the stomach are accompanied by histamine achlorhydria.

CYTOLOGIC SMEAR

A positive Papanicolaou⁵ smear of the gastric sediment demonstrating cancer cells is of immense importance if the interpretation is made by a competent technician. If the smear is positive, the lesion is almost sure to be cancer, since Graham et al.⁶ found only 4 per cent false-positive tests. If the smear is negative, cancer may still be present since approximately a third of the carcinomas of the stomach fail to show cells when usual methods are employed. Careful preparation of specimens diminishes this error,⁶ and it is possible that further experience with such substances as

eugenol will increase the accuracy of this test even more

The presence of an accompanying active duodenal ulcer is strong evidence that the gastric ulcer is benign. Figures from the Mayo Clinic^{7, 8} indicate that 0.1 per cent of patients with duodenal ulcer will have carcinoma of the stomach, and 1 per cent of those with duodenal ulcer will have an associated benign ulcer of the stomach.

The presence of multiple gastric ulcers also suggests that the lesions are benign. However, all combinations of ulcer and cancer are seen occasionally, with multiple benign ulcers, associated benign duodenal or gastric ulcer and distinct carcinoma, and multiple ulcerating carcinomas.

In this series multiple gastric ulcers were found in 8 per cent of the patients. Four distinct ulcers were present in one case. Four per cent of the patients had associated gastric and duodenal ulcers.

COMPLICATIONS OF GASTRIC ULCERATION

Incidence

Massive hemorrhage appears to be slightly less frequent with malignant ulcers than with benign since it occurred in only 6 per cent of the cases of ulcer-cancer, compared with benign ulcer, in which the incidence was 9 per cent. On the other hand, pyloric obstruction was much more common, occurring in 19 per cent of the ulcer-cancer group, and in only 1.2 per cent of the benign cases. Perforations, nearly always walled off by adjacent viscera, occur with about equal frequency in both groups.

RATE OF HEALING

The rate of healing of a gastric ulcer is still regarded as the most reliable differential feature between benign ulcer and cancer. Even this fact is not absolute, since in this series two ulcers apparently healed entirely under hospital care but recurred shortly thereafter, and resection proved them to be carcinoma. These rare cases, however, are exceptions to the rule that only benign ulcers tend to heal rapidly. It is also true that some ulcers that prove to be benign fail to heal in a period of months, especially in the older age groups.

This method of differentiation has been applied in a large number of cases in this hospital. In patients that have done well under medical management, significant improvement is usually apparent after a three-week interval. Although complete healing is rare at this time, it occasionally occurs. The average ulcer has healed completely in two months, although at times as long a period as four months is required before the lesion entirely disappears. Consequently, the decision to abandon or continue medical treatment must usually be made a month after the patient is admitted to the hospital. In individual cases, especially in older patients, it may be necessary to wait longer for heal-

ing. Such patients must be followed closely, however, until healing is complete.

The proponents of immediate operation for all gastric ulcers⁹ maintain that this delay is very dangerous from the point of view of spread of misdiagnosed cancers during the interval. On the other hand, it may be pointed out that since the average duration of symptoms before the patient arrives in the hospital is one and a half years, the relatively short extra delay should impose little hazard.

This point obviously cannot be proved by statistics. But it is of interest that of the patients who were believed to have benign ulcer but who were operated on with a delay of less than one month after reaching the hospital, 40 per cent are living and well five years later, of those who were followed for six months or more and then were found to have cancer at operation, all are dead of the disease.

In summary, it is certain that the differential diagnosis of ulcer and cancer cannot be made by present technics in about 10 per cent of the cases. From the point of view of cancer control all gastric ulcers should therefore be operated on at once. However, with care, it is possible to select a small group that can be managed medically if they are closely followed. Following these principles, 97 per cent of the patients who had resections for gastric ulcer were treated correctly. It is of interest that the 9 patients in this series who were followed an inordinate period before resection (the errors in judgment) were exactly equal in number to the deaths after resection.

Types

The complications of gastric ulcer are the same as those of duodenal ulcer, but vary in certain respects. *Perforation* of a chronic gastric ulcer along the lesser curvature is nearly always so gradual that the liver or pancreas walls off the lesion so closely that a general peritonitis does not occur. On the other hand, perforations of so-called acute gastric ulcers close to the pylorus are nearly all duodenal perforations. These free perforations into the peritoneal cavity follow the same course, whether they originate on the duodenal or gastric side of the pyloric vein. *Obstruction* may occur either at the pylorus or, rarely, at an hourglass constriction. In this series, no cases of the latter type were observed. It should also be noted that though reflex vomiting is common with gastric ulcer, pyloric obstruction significant enough to be noted by x-ray examination is much more likely to be due to duodenal ulcer or gastric cancer than it is to gastric ulcer. The demonstration of a gastric ulcer by x-ray study combined with the clinical findings of partial or total pyloric obstruction is therefore an absolute indication for operation. *Hemorrhage* is by far the most common and important complication, occurring as massive bleeding in almost exactly

enough for a final diagnosis to be made. Consequently, the cases reported below, in which an aggressive surgical attack has led to resections in nearly 60 per cent of the entire series, are especially significant.

In this group, 34 of the 512 cases originally diagnosed as gastric ulcer were finally found to be cancer. This was an over-all diagnostic error of 6.6 per cent. Of the patients who had resections and therefore final diagnoses, 32 out of 295, or 10.8 per cent, were proved to have cancer (Table 2).

TABLE 2 *Error in Diagnosis of Cancer*

GROUP	ORIGINAL DIAGNOSIS OF BENIGN ULCER	FINAL DIAGNOSIS OF CANCER	ERROR IN DIAGNOSIS %
All cases	512	34	6.6
Cases with resections	295	32	10.8

The absolute diagnostic error therefore now lies between 6.6 and 10.8 per cent, and we believe that it is very near to 10 per cent. Since the error in a previous study was at least 14 per cent,³ there has been definite improvement during the past decade. It is pertinent to inquire why this change has occurred and to discuss briefly the differential diagnosis of benign ulcer and cancer.

In the first place, it is well to emphasize that the clinician is almost wholly at the mercy of the radiologist and gastroscopist so far as diagnosis is concerned. To illustrate this point, it may be noted as shown previously³ that 65 per cent of the lesions in the prepyloric area that demonstrate ulceration are cancer. But, at present, with the use of spot films, when a highly competent radiologist calls an ulcer in this area benign, his diagnostic error will be approximately 10 per cent.

No one appreciates his limitations in this respect more than the radiologist, who realizes his inability to make a microscopical diagnosis. It has therefore become the custom to report this group of ulcers as "gastric ulcer, grossly benign." The gastroscopist is limited in the same fashion. To their interpretations, data of less diagnostic importance may be added, including the duration of symptoms, the location of the lesion, the size of the ulcer, the gastric analysis, the cytologic smear of the gastric contents, the presence or absence of accompanying ulcers or complications, and the rate of healing under medical therapy to help distinguish ulcers that are microscopically benign from ulcers that are microscopically malignant ("ulcer-cancer").

AGE AND DURATION OF SYMPTOMS

A short gastric history in a patient fifty years of age or over is highly suggestive of cancer. The average duration of symptoms in patients with "ulcer-cancer" before entry to the hospital is one

and a half years, compared with a duration of five years in patients with benign ulcers. The duration of symptoms with "ulcer-cancer" varied from less than a month to ten years. The ages varied from twenty-six to seventy-seven years for ulcer-cancer, whereas the average age of the entire group was fifty-one years.

LOCATION OF THE LESION

Increasing accuracy in x-ray technic has resulted in the differentiation of many of the benign ulcers and ulcerating carcinomas, especially in the prepyloric area. At present the diagnosis of benign ulcer in the pyloric and prepyloric areas is nearly as accurate as and the error in diagnosis of cancer not much higher than that of lesions on the mid-lesser curvature. Schatzki and Eyster⁴ have found, in an independent review of the same cases, that the radiologic diagnostic error of gastric lesions throughout the stomach is highest in the region of the cardia, less in the prepyloric area and least along the mid-lesser curvature. It is of interest to note that in the period from 1938 to 1947, 6 benign ulcers of the greater curvature were resected.

SIZE OF THE ULCER

Although previous studies have shown that the incidence of cancer increases with the size of the ulceration, very little attention should be paid to this feature in the individual case. It is apparent that early operation will increase the number of resected small ulcerating carcinomas. In this series, the average diameter of the malignant ulcer was 1.8 cm., and only 1 was over 2.5 cm. The benign ulcers that were resected averaged 1.6 cm., and the largest benign ulcer was 7.0 cm. in diameter.

GASTRIC ANALYSIS

The presence of free hydrochloric acid is of no significance although its absence after the use of histamine is strongly suggestive of cancer. Free hydrochloric acid is found in approximately 90 per cent of the patients with benign ulcer and of those with ulcer-cancer. About 40 per cent of carcinomas of the stomach are accompanied by histamine achlorhydria.

CYTOLOGIC SMEAR

A positive Papanicolaou⁵ smear of the gastric sediment demonstrating cancer cells is of immense importance if the interpretation is made by a competent technician. If the smear is positive, the lesion is almost sure to be cancer, since Graham et al.⁶ found only 4 per cent false-positive tests. If the smear is negative, cancer may still be present since approximately a third of the carcinomas of the stomach fail to show cells when usual methods are employed. Careful preparation of specimens diminishes this error,⁶ and it is possible that further experience with such substances as

eugenol will increase the accuracy of this test even more

The presence of an accompanying active duodenal ulcer is strong evidence that the gastric ulcer is benign. Figures from the Mayo Clinic^{7, 8} indicate that 0.1 per cent of patients with duodenal ulcer will have carcinoma of the stomach, and 1 per cent of those with duodenal ulcer will have an associated benign ulcer of the stomach.

The presence of multiple gastric ulcers also suggests that the lesions are benign. However, all combinations of ulcer and cancer are seen occasionally, with multiple benign ulcers, associated benign duodenal or gastric ulcer and distinct carcinoma, and multiple ulcerating carcinomas.

In this series multiple gastric ulcers were found in 8 per cent of the patients. Four distinct ulcers were present in one case. Four per cent of the patients had associated gastric and duodenal ulcers.

COMPLICATIONS OF GASTRIC ULCERATION

Incidence

Massive hemorrhage appears to be slightly less frequent with malignant ulcers than with benign since it occurred in only 6 per cent of the cases of ulcer-cancer, compared with benign ulcer, in which the incidence was 9 per cent. On the other hand, pyloric obstruction was much more common, occurring in 19 per cent of the ulcer-cancer group, and in only 1.2 per cent of the benign cases. Perforations, nearly always walled off by adjacent viscera, occur with about equal frequency in both groups.

RATE OF HEALING

The rate of healing of a gastric ulcer is still regarded as the most reliable differential feature between benign ulcer and cancer. Even this fact is not absolute, since in this series two ulcers apparently healed entirely under hospital care but recurred shortly thereafter, and resection proved them to be carcinoma. These rare cases, however, are exceptions to the rule that only benign ulcers tend to heal rapidly. It is also true that some ulcers that prove to be benign fail to heal in a period of months, especially in the older age groups.

This method of differentiation has been applied in a large number of cases in this hospital. In patients that have done well under medical management, significant improvement is usually apparent after a three-week interval. Although complete healing is rare at this time, it occasionally occurs. The average ulcer has healed completely in two months, although at times as long a period as four months is required before the lesion entirely disappears. Consequently, the decision to abandon or continue medical treatment must usually be made a month after the patient is admitted to the hospital. In individual cases, especially in older patients, it may be necessary to wait longer for heal-

ing. Such patients must be followed closely, however, until healing is complete.

The proponents of immediate operation for all gastric ulcers⁹ maintain that this delay is very dangerous from the point of view of spread of misdiagnosed cancers during the interval. On the other hand, it may be pointed out that since the average duration of symptoms before the patient arrives in the hospital is one and a half years, the relatively short extra delay should impose little hazard.

This point obviously cannot be proved by statistics. But it is of interest that of the patients who were believed to have benign ulcer but who were operated on with a delay of less than one month after reaching the hospital, 40 per cent are living and well five years later, of those who were followed for six months or more and then were found to have cancer at operation, all are dead of the disease.

In summary, it is certain that the differential diagnosis of ulcer and cancer cannot be made by present technics in about 10 per cent of the cases. From the point of view of cancer control all gastric ulcers should therefore be operated on at once. However, with care, it is possible to select a small group that can be managed medically if they are closely followed. Following these principles, 97 per cent of the patients who had resections for gastric ulcer were treated correctly. It is of interest that the 9 patients in this series who were followed an inordinate period before resection (the errors in judgment) were exactly equal in number to the deaths after resection.

Types

The complications of gastric ulcer are the same as those of duodenal ulcer, but vary in certain respects. *Perforation* of a chronic gastric ulcer along the lesser curvature is nearly always so gradual that the liver or pancreas walls off the lesion so closely that a general peritonitis does not occur. On the other hand, perforations of so-called acute gastric ulcers close to the pylorus are nearly all duodenal perforations. These free perforations into the peritoneal cavity follow the same course, whether they originate on the duodenal or gastric side of the pyloric vein. *Obstruction* may occur either at the pylorus or, rarely, at an hourglass constriction. In this series, no cases of the latter type were observed. It should also be noted that though reflex vomiting is common with gastric ulcer, pyloric obstruction significant enough to be noted by x-ray examination is much more likely to be due to duodenal ulcer or gastric cancer than it is to gastric ulcer. The demonstration of a gastric ulcer by x-ray study combined with the clinical findings of partial or total pyloric obstruction is therefore an absolute indication for operation. *Hemorrhage* is by far the most common and important complication, occurring as massive bleeding in almost exactly

the same proportion of cases as with duodenal ulcer¹⁰

A history of hemorrhage of varying degrees of severity was encountered in approximately 30 per cent of this series. On the other hand, evidence of recent bleeding was found in only 16 per cent of the cases. The majority of patients entering with hemorrhage demonstrated by a hemoglobin of less than 10 gm per 100 cc or a red-cell count below 3,000,000 that they had bled severely. The history and further laboratory studies indicated that the anemia was the result of a slow, persistent blood loss in many cases. In the remainder, a total of 46 cases, the hemorrhage had been sudden and massive.

It is extremely important, from a surgical point of view, to segregate these patients with massive hemorrhage. For it is in this group that emergency surgical procedures must often be undertaken as life-saving measures. Although a complete discussion of the management of upper gastrointestinal hemorrhage is impossible in this short survey, the salient features of bleeding gastric ulcers may be noted.

During this period, the attitude toward these cases in the Massachusetts General Hospital has been essentially conservative. Quite in contrast to Stewart's¹¹ aggressive attack, these patients on the wards usually have been admitted to the Medical Service. If bleeding did not stop, or if it recurred, surgical consultation was requested. This simple plan has, in practice, been subject to so many delays that occasionally lives have been lost before operative measures have been instituted. The liaison has been much closer in the private sections so that operative delay has been less. This diversity of opinion has, perhaps fortunately, provided two distinct categories of treatment: one in which operation is reserved for patients whose hospital course demonstrates that they will die otherwise, and the other (described previously by Allen¹⁰), which nearly always demands early operation in the patients over forty-five years of age.

Several facts that have emerged may be stated. The history of a previous hemorrhage does not aid in the determination of the severity of the present episode. Likewise, bleeding that is apparently trivial on entry may develop into massive hemorrhage under observation. Sex does not appear to alter these factors.

The age of the patient is generally believed to be of great importance in prognosis. In this particular group, the number of patients who died from hemorrhage was so small that this factor cannot be assessed significantly. The age of the patients who recovered spontaneously without operation was fifty-seven years, that of those who required surgery to stop the bleeding was also fifty-seven years, and that of the few who died from hemorrhage was sixty-eight years. This may mean

either that hemorrhage is more fatal in old age or that surgery is not requested or advised as frequently in the aged. Furthermore, the age factor is much less important with gastric ulcer, since the incidence of bleeding gastric ulcer below the age of forty-five is very low. Thus, 90 per cent of the massive hemorrhages occurred in patients over forty-five years of age. Of the patients below forty-five, one required an emergency resection, one had an interval resection, and the other recovered spontaneously; there were no deaths in this younger group.

The preoperative diagnosis of gastric ulcer in the presence of massive hemorrhage is often very difficult. Early x-ray studies will show the ulcer in about half the cases, and are of additional value in the elimination of esophageal varices, hiatal hernia or duodenal ulcer as the source of bleeding. The accuracy of x-ray study is increased by later interval examinations, but in 4 cases (9 per cent of those with massive hemorrhage), the ulcer was never demonstrated. Hence, the surgeon, at the time of laparotomy, is often confronted with a stomach that appears entirely normal. He must realize that superficial erosions, especially in the prepyloric area, may bleed massively, and that cirroid aneurysms of the left gastric artery may rupture through microscopic ulcers in the mucosa. Obviously, in these cases, a careful pathological examination will be necessary to establish the diagnosis, and the surgeon is required to explore by a gastrotomy incision or to resect a stomach that appears grossly normal.

Fortunately, gastric resection for actively bleeding gastric ulcer is much less hazardous than that for bleeding duodenal ulcer. This is due to the lack of technical difficulty about the duodenal stump and to the fact that hemorrhage can be controlled in an absolute fashion. Despite the fact that only one of the operations in this group was carried out within forty-eight hours of onset of the hemorrhage, postoperative complications have been rare.

The results in this series may be summarized as follows. 58 patients entered the hospital with gastric ulcer and severe anemia. Four patients died of massive hemorrhage from a gastric ulcer, proved by autopsy, without operation, in retrospect it appears that early surgery might have saved 2 of them. Twenty-eight patients survived without operation, and 26 were operated on during the initial hospital admission. The condition of the majority of the patients had been improved considerably before operation, but in 9 cases operation was carried out as an emergency measure in the presence of active bleeding. There was only one postoperative death, and that followed a late attack on an ulcer that had bled repeatedly on the medical wards.

The over-all death rate from hemorrhage was therefore approximately 9 per cent. In patients

treated surgically it was 4 per cent, whereas in those treated conservatively, it was 12.5 per cent. Consequently, it appears that surgery can be carried out in this group of patients with relatively little hazard and with better results.

It is our belief that there are three groups of patients with gastric ulcer who require emergency operation. A patient admitted with massive upper gastrointestinal bleeding should be given a careful x-ray examination, palpation being avoided, as soon as stabilization has occurred. If a positive diagnosis of gastric ulcer is obtained, and the patient has been bleeding less than forty-eight hours, immediate operation is indicated. If he has been bleeding for a longer time but the hemorrhage stops soon after hospital admission, a period of observation and medical treatment is advised in the expectation that normal blood and nutritional levels may be reached and gastric resection carried out at a time of election. Immediate operation is indicated in this group if a recurrent hemorrhage occurs at any time. In a third, small group, the gastric hemorrhage fails to stop after the patient arrives in the hospital, and operation is indicated soon after his arrival. The same operative indications hold true in the absence of a positive x-ray diagnosis of ulcer provided pathologic lesions of the esophagus, especially varices, and blood dyscrasias can be excluded.

OPERATIONS FOR GASTRIC ULCER

Indications

If it is conceded that any gastric ulcers are to be treated medically, it would be well to define as accurately as possible the groups of patients that are likely to do well and those that will do poorly on conservative therapy. Unfortunately, this is impossible, except in very general terms. An analysis of all the features of the two groups shows that they are nearly exactly similar, and that it cannot be foretold in the great majority of cases what the response to therapy will be. Thus, the sex and age distributions, the location of the ulcer, the incidence of achlorhydria and the presence of occult blood in the stools are strikingly similar. It does appear that the particular ulcers that do poorly on medical treatment are the larger ones, particularly those that are over 2.5 cm in diameter, those that are associated with obstruction, and those that are recurrent with a long history of gastric symptoms.

It is suggested, therefore, that a trial of medical therapy be reserved for patients in whom an excellent radiologist and gastroscopist indicate that the ulcer is grossly benign and who have a duration of symptoms of less than one year, an ulcer that is 1 cm or less in diameter, located on the lesser curvature, and a negative cytologic smear. If the x-ray diagnosis is equivocal or not of the highest

quality, ulcerative lesions in a stomach with histamine achlorhydria or those that are found elsewhere than on the lesser curvature or high in the cardia should also be singled out for immediate surgery. It will be observed that patients with ulcers in the cardia are permitted a period of medical therapy despite the fact that the incidence of cancer is high, this is done because the operative mortality for lesions in this particular location is still great enough to counterbalance the error in diagnosis of cancer. The failure of any of these ulcers to heal, as stressed above, is an absolute indication for surgery.

Types

Any operative procedure for gastric ulcer must satisfy two criteria. It must change the gastric physiology in such a fashion that recurrent ulceration cannot follow, and it must be extensive enough that an adequate operation will have been done if cancer is found on microscopical examination of the specimen. It follows that such operations as gastroenterostomy and vagotomy have no place in the treatment of gastric ulcer, and that some type of gastric resection is indicated when surgery is undertaken.

A satisfactory resection consists of the excision of an adequate section of stomach on either side of the ulcer together with the regional lymph nodes along both curvatures. We believe this is accomplished most satisfactorily by the removal of both the greater and lesser omenta together with at least 50 per cent of the stomach. Furthermore, it has been found that sleeve resections are not satisfactory because the gastric physiology is not altered sufficiently and a recurrent ulcer may occur. Clinical experience has shown that the antral mucosa exerts a great influence on gastric secretion. Thus, if a Finsterer exclusion procedure is carried out for duodenal ulcer, with the line of distal section through the antrum, and with retention of the antral mucosa, a postoperative jejunal ulcer can be expected in nearly every case. It is obvious that this operation is used very rarely for gastric ulcer, since it is usually easier to divide the duodenum. However, it was employed in one case in this series, and the patient thereafter developed a recurrent gastric ulcer near the anastomosis. Relief followed resection of the retained antrum. The importance of the antrum has been confirmed by Ransom,¹² who reported 4 anastomotic ulcers following gastric resection for gastric ulcer, and in 3 of them the resections were incomplete since the antral mucosa was retained.

Resection of the distal portion of the stomach, including the ulcer and at least 2 cm of normal mucosa proximal to it, is possible in most cases. If a narrower margin is necessary because of the proximity of the esophagus, immediate pathological examination with a frozen section is advisable. We

agree with Marshall and Welch¹³ that mobilization of the left gastric artery often makes an apparently high ulcer relatively easy to resect. However, there remains a group of ulcers near the cardia and in the fundus that cannot be excised by this method, and it is this group that now can be treated adequately by resection of the proximal portion of the stomach.

The high ulcers include about 10 per cent of all gastric ulcers. As noted above, increasing experience with this group has shown that the differential diagnosis of cancer over the ulcer is especially difficult in this section of the stomach. Heretofore, only two solutions have been available—total gastric resection and distal partial gastric resection with retention of the high ulcer.

Total gastric resection has been employed, and will continue to be used for certain gastric ulcers that are believed to be extensive carcinoma. The end-results prove, however, that this operation is to be avoided, when possible, for benign lesions.

TABLE 3 *Operative Mortality*

OPERATION	No OF CASES	No OF DEATHS	MORTALITY	
			%	
Partial distal gastrectomy	269	6	2	2
Partial proximal gastrectomy	14	3	21	0
Total gastrectomy	4	0	0	0
Miscellaneous	8	0	0	0
Totals	295	9		
Average			3	0

Varying degrees of malnutrition and anemia, as pointed out by MacDonald, Ingelfinger and Belding,¹⁴ occur postoperatively and have, in certain cases, proved troublesome.

Since the antral mucosa is so important in the formation of ulcers, Madlener¹⁵ suggested that a resection of the distal stomach could be done for a high ulcer with the expectation that it would heal spontaneously thereafter. The operation was revived by Colp,¹⁶ who reported favorable results in 8 cases. This procedure has not found favor elsewhere since it not only fails to eliminate the possibility of cancer but also has not affected healing in certain cicatrized ulcers.

More recently two other methods of attack have been developed. Vagotomy has been suggested as of particular value in the inaccessable group of ulcers. This procedure may give a false sense of security that is quite unjustifiable. We cannot agree that it has any place in the treatment of the lesions that frequently turn out to be cancer.

The final method appears the most logical in this group. It involves a proximal partial gastric resection, including the ulcer, with an esophago-gastric anastomosis. Developed concomitantly with the operative attack on carcinoma of the cardia and lower esophagus, Churchill and Sweet¹⁷

have described the technic that is followed for all lesions in this location. In this series, 14 cases of high gastric ulcer have been treated by this method, chiefly by Dr. Richard H. Sweet.

Theoretically, this operation has several features that will make the late follow-up results of great interest. Thus, the antral mucosa is retained—definitely a hazard in any other type of ulcer operation. Since a vagotomy is automatically done by the nature of the operation, as well as a removal of a large portion of the acid-bearing fundus, it is probable that the ultimate results will prove satisfactory. Studies of gastric secretion of several of these patients are now under investigation by Jones and Culver¹⁸ and will be reported later by them.

Removal of these high ulcers by proximal resection is accompanied by a greater risk than that of partial distal resection and is followed by more post-operative symptoms. Follow-up results have been obtained in 10 of the 11 patients who survived operation. There are no recurrent ulcers in the group. Four are entirely asymptomatic. The others complain of various symptoms that are trivial in 4 and severe in 2. They consist of fullness on the ingestion of small amounts of food, and regurgitation of small amounts of mucus and bile early in the morning.

Complications and Mortality

With the exception of the fatal cases, the postoperative complications were, in general, of little importance. The mortality of partial distal gastric resection was 2.2 per cent (Table 3). The 6 deaths were due to local sepsis (2 cases), pneumonia (2 cases), acute pancreatitis (1 case) and appendicitis with perforation (1 case). After trans-thoracic partial proximal resection the mortality was 21 per cent. There were 3 deaths: 1 patient succumbed of postoperative shock, 1 of coronary thrombosis, and 1 (who also had a resection for carcinoma of the esophagus) of massive pulmonary embolism.

RESULTS

With the exception of the proximal partial gastric resections, no elaborate attempt has been made to carry out complete follow-up studies in this group of patients, since this work is in progress and will be reported elsewhere.¹⁹ The general trends of conservative therapy, however, are indicated in the following figures, comprising the years 1940-1946. Eleven per cent of the entire group of patients did well on medical therapy. In 14 per cent the results were probably good, but were indeterminate since the patients did not return long enough to the outpatient department for us to be sure that the ulcer remained healed. Twenty per cent did poorly and refused further treatment or required surgery.

Surgical therapy was carried out at some time in 58 per cent of the entire series. A small group of 8 patients had miscellaneous operations. Two

had a vagotomy, 1 is apparently cured, whereas the other has a recurrent ulcer. Gastrotomies were carried out in 2 patients, no ulcer being demonstrated, one of them did well, and the other has radiologic and clinical evidence of recurrent ulcer. Three patients had a gastroenterostomy, one of them died later, probably of cancer, another had a massive hemorrhage two years later, and the third has been lost. One patient who had a local excision of an ulcer for massive hemorrhage did well.

Gastric resections were carried out in 295 cases. Four of the patients had a total gastrectomy — loss of weight and inability to maintain nutrition are common in this group. The remainder had partial gastrectomies. After recovery from resection, only 1 patient has required reoperation. That patient, mentioned above, developed a recurrent gastric ulcer following a Finsterer exclusion procedure for massive hemorrhage. One patient developed an anastomotic ulcer two years after an adequate subtotal gastrectomy. This jejunal ulcer responded rapidly to medical therapy. The possibility of an anastomotic ulcer was raised in 3 other cases, but in none could a crater be discovered on x-ray examination and all patients recovered promptly on conservative therapy.

Follow-up studies, still incomplete, indicate that approximately 75 per cent of the patients will be asymptomatic after partial gastric resection. Fifteen per cent will have trivial gastric symptoms, easily controlled by diet. Ten per cent will have symptoms of a small stomach, lack of appetite or gastric distress and loss of strength, endurance or weight that will require medical care. These conclusions agree with those of Ransom,¹² but are slightly less favorable than those of Walters and Clagett,²⁰ who report uniformly excellent results after subtotal resection for gastric ulcer.

SUMMARY AND CONCLUSIONS

Several trends in the management of gastric ulcer have become apparent in the past few years. It has been shown that the term "peptic ulcer" should be eliminated, and that gastric ulcer is a distinct entity not to be confused with duodenal ulcer. It has also been demonstrated that gastric ulcer still cannot be differentiated from cancer in nearly 10 per cent of the cases. Although improved diagnostic methods have tended to reduce this

error, the mortality of operation has simultaneously declined to minimum levels.

To the surgeon interested in cancer control, these tendencies make gastric resection advisable for all gastric ulceration. The physician, on the other hand, is tempted to treat these ulcers medically, stressing the operative mortality, low though it may be, the discomforts of operation and the post-gastrectomy symptoms that may appear.

If medical therapy is elected, such cases must be carefully selected, studied by the best radiologist and gastroscopist available, and followed vigilantly, with early recourse to surgery if healing is not prompt. The physician must realize that new operative techniques provide satisfactory excisional surgery for ulcers of the cardia and that radical surgery for the most common complication of gastric ulcer — hemorrhage — is both safe and desirable.

From the principles outlined above, it appears that surgical therapy is indicated in approximately 75 per cent of the patients with gastric ulcers and that excellent results are to be expected after gastric resections.

PATHOLOGY AND PATHOGENESIS

A brief description of the pathology of chronic pneumonitis due to mineral oil follows, to call attention to the factors that will enable one to make a clinical diagnosis in the ambulatory adult. It has been shown that the severity of the reaction in the lung to aspirated oil depends upon the character of the oil.¹²⁻¹⁴ When saponifiable oils enter the lower respiratory tract, the type of immediate reaction is due to the amount of fatty acid present or produced from the aspirated oil by tissue enzymes. Mild vegetable oils, like poppy-seed oil, olive and sesame oils cause the least reaction. On the other hand, cod-liver oil, lard and animal fats are capable of producing sudden and violent reactions, with hemorrhage and necrosis. The response of the lung to liquid petrolatum, a non-saponifiable oil, is extremely mild, amounting to a foreign-body reaction to an inert substance within and around the alveoli in which the oil settles. The final stage in this pathologic process is fibrosis of the lung occurring first as a mere thickening and infiltration of the alveolar septum and later going on to form fibrous nodules, some tubercle-like, around large collections of lipoid material. A proliferative rather than a necrotizing pneumonia is the rule after repeated aspiration of liquid petrolatum. Occasionally, the proliferative pneumonitis takes on the pathological and x-ray appearance of a circumscribed, uniformly dense tumor mass surrounded by a concentric fibrotic ring to which Ikeda¹⁵ has given the name "paraffinoma."

The presence of free oil in the alveoli in pneumonitis due to mineral oil is so striking that oil may be found at the surface of the preserving fluid shortly after a cut section of the involved lung is placed in a laboratory jar containing the fluid. This phenomenon helped to focus the attention of pathologists on the existence of this uncommon disease.

Microscopically, macrophages filled with oil may be found in the alveolar spaces, in the lymphatics and in the hilar lymph nodes. The last, however, are rarely appreciably enlarged even in the later stages of oil-aspiration pneumonia. Pleural reactions, too, are extremely uncommon, and if they occur are usually secondary to superimposed infection.

It is not difficult to see that the disposition of the aspirated oil is dependent largely upon gravity and inspiration suction. Accordingly, the mineral-oil pneumonitis in the ambulatory adult will be found as a rule at the lung bases, more on the right than the left, and ultimately in both lower-lung fields.

SYMPTOMS, SIGNS AND COURSE

A remarkable paucity of symptoms referable to the respiratory tract is elicited on close questioning, even when the pulmonary involvement is far advanced. Certainly the patient is asymptomatic

when the process in the lungs is in its incipency. It is uncommon for this low-grade pneumonitis to be complicated by symptoms of suppuration of the lungs or bronchiectasis. As might be expected, some of the patients may be subjected to recurrent acute pneumonias superimposed upon the oil pneumonitis. As the pulmonary reaction to the liquid petrolatum piles up to an imposing radiographic appearance, the patient becomes noticeably dyspneic on exertion and may develop a hacking cough. However, because of age, the dyspnea and cough may be attributed to arteriosclerotic heart disease. Or, if the pulmonary disease is discovered for the first time on x-ray study and found to be one sided, a diagnosis of carcinoma of the bronchus may be made.

The striking thing about this benign disease in most ambulatory adults is the good nutrition, comfort and general well-being of the patient in the presence of even extensive pulmonary involvement. Likewise, it is also remarkable that, given the x-ray findings in a proved case of mineral-oil pneumonitis, re-examination of the involved lungs will disclose only scant and unrevealing signs on inspection, percussion and auscultation.

FLUOROSCOPY AND CHEST X-RAY STUDY

The earliest involvement of the lungs by the chronic aspiration of liquid petrolatum causes no localized findings on the chest film or only increased markings. As the oil continues to spill over into the lungs, a small, basal, infiltrative process, looking not unlike a bronchopneumonic lesion, soon appears. At times, the early process seen on the x-ray film has a hard appearance, owing to the intense proliferative reaction around the oil-containing alveoli. The picture, as in one of the cases reported below, may resemble that seen long after bronchography has been done with a radio-opaque oil in the pulmonary area, and a fine residuum of that substance has been left.

As the pneumonitis progresses, the infiltrations fuse into an ill defined area of ground-glass density, or the density may become circumscribed (paraffinoma formation). As a rule, no associated indirect evidence of atelectasis is apparent, nor is hilar adenopathy noted. The latter features are worth bearing in mind in the differentiation of this benign disease from a neoplastic process.

On fluoroscopy, both leaves of the diaphragm move freely, their contour is not appreciably altered, and the heart and the mediastinum are situated in the normal position. Diaphragmatic changes will occur, however, in late oil pneumonitis as a result of secondary infection and compensatory emphysema.

In these ambulatory patients, radiographic extension of the lesion is to be expected as is ultimate involvement of both lung fields while the patient continues on the oil regimen. A sudden regression

PULMONARY HAZARD OF THE INGESTION OF MINERAL OIL IN THE APPARENTLY HEALTHY ADULT

A Clinicoroentgenologic Study, with a Report of Five Cases

LOUIS SCHNEIDER, M D *

MT VERNON, NEW YORK

PERIODIC reports of harm resulting from the ingestion or aspiration of mineral oil have appeared in the medical literature and even in the lay press. Recently, it has been shown that the taking of liquid petrolatum with food prevents substantial amounts of food carotene, a precursor of vitamin A, from entering the body.¹ This fact and some corollaries thereto have been established to the satisfaction of authors of the latest books on nutrition and vitamin therapy and have provoked editorial comment.²

More than two decades have elapsed since it was demonstrated that serious harm can be done to the lungs by the introduction of mineral oil into the nose or throat in pure form or as a vehicle for other medicaments.³ This source of chronic aspiration pneumonitis, or so-called lipid pneumonia, was described as occurring especially in infants and young marantic children.⁴ The use of this hydrocarbon in nose and throat medication was thereupon officially condemned by the New York City Health Department. Soon, intranasal instillation of liquid petrolatum was shown to be equally harmful to adults and children,⁵ and the reversibility of the pulmonary process following the withdrawal of this treatment was demonstrated.

Then it was found that a chronic pneumonitis can be induced by ingestion of mineral oil as a laxative over a long period. Characteristic pulmonary lesions were encountered in debilitated, recumbent and aged persons, in persons suffering from dysphagia of nervous origin and in patients in whom neoplastic or other destructive processes involved the mouth or throat. This accounts for the large series of cases of lipid pneumonia reported from hospitals for the chronically sick⁶ and the aged and infirm,⁷ and wisely led to the abandonment of the use of mineral oil as a habitual laxative for these patients. It is interesting to note in this connection that liquid petrolatum as a laxative has accounted for nearly half the adult cases of oil-aspiration pneumonia reported thus far and that half the series of 264 cases of this pulmonary disease compiled by Sweeney⁸ in 1942 were found in adults.

It is the purpose of this paper to emphasize the pulmonary hazard to apparently healthy and ambulatory adults inherent in the habitual use of mineral oil by ingestion. Indeed, the broncho-

pulmonary process in these persons comes on so insidiously that it may be uncovered only on a tuberculosis case-finding x-ray survey. It is not a new clinicoroentgenologic phenomenon that prolonged ingestion of this hydrocarbon for laxative or other purposes (one patient said he took mineral oil for the tonic effect it had on him — he called it "poor man's olive oil") can cause chronic pneumonitis in the apparently healthy adult. Individual cases in which the diagnosis has not been made ante mortem or preoperatively have been reported even till recently. Commonly if the pneumonitis is one sided in these older adults, the examining physician often makes a diagnosis of bronchogenic carcinoma,⁹ ¹⁰ only to find evidence of oil-aspiration pneumonia in the removed lung specimen. It is to be hoped that the index of suspicion of this insidious man-made disease will increase. It is reasonable to conclude that many cases of benign pneumonitis in the apparently healthy are going undetected if 5 such patients have been seen by one observer in a two-year period.

Recently, 2 cases of oil pneumonitis in healthy adults who were normal neurologically except for the finding of an absent gag reflex were reported.¹¹ In 2 other cases, cited below, the gag reflex was markedly diminished, and in still another some dysphagia was associated with the presence of a Zenker diverticulum. Although careful examination of the throat in apparently well older persons might show some abnormality causing the spilling over into the larynx of ingested liquid petrolatum, it has been demonstrated that this substance is so bland that, introduced into the nasopharynx, it can find its way into the lungs without causing symptoms of irritation, such as cough.¹² Serial x-ray films in these cases indicate that it probably takes a long time for a radiologically visible reaction to occur in the lung into which oil aspiration has taken place. Once developed, however, the pneumonitis slowly increases as long as the patient continues on the oil laxative regime. In these apparently healthy persons, only a minute quantity of the oil gets down into the lower order of bronchi at one time, and as time goes on some of it is fortunately removed by expectoration and to a lesser degree by phagocytosis. One patient with lipid pneumonia exhibited no roentgenologically detectable trace of this product in his bronchi shortly after ingestion of 20 cc of iodized oil.

*Chief Chest Service, Washington Heights Chest Clinic, New York City; Department of Health, attending physician, Tuberculosis Section, Vanderbilt Clinic.

The first test is an examination of the sputum for oil droplets. This procedure should be carried out some days after the patient has ceased taking mineral oil. Into a clean, wide-mouthed jar, the patient expectorates before breakfast for three successive days after thoroughly washing his mouth and throat with physiologic saline solution. He keeps this jar in the refrigerator concealed in a paper bag so that the contents do not offend the ice-box raider. Two analyses may then be done with this accumulated sputum. If oil droplets are present, placing cigarette paper or a piece of lens paper on the surface of the expectorated material will bring out the tell-tale grease spots on the paper. Now, if a sample of the sputum is examined under the microscope, the contained mineral oil droplets will take the characteristic stain with scarlet red. Saponifiable fats and oils, on the other hand, take the osmic acid stain.

The second confirmatory test is an aspiration biopsy of the affected lung. This procedure when wisely employed is comparatively safe,^{7, 16} the chief danger and discomfort being the induction of a pneumothorax. The region to be punctured is carefully mapped out under fluoroscopic control. Procaine is injected into the skin, and a needle of 16 or 17 bore is plunged quickly into the involved lung parenchyma. Suction should then be applied until a little bloody material is drawn into and mixed with the procaine in the barrel of the syringe. The needle is then just as quickly withdrawn. Holding the syringe vertical for a while against a bright light with the needle upward, one can see oil droplets on the surface of the bloody fluid if the biopsy has been properly performed. In a case of lipid pneumonia, to determine if the oil seen is liquid petrolatum, microscopical examination may then be performed with the use of scarlet-red stain.

TREATMENT

It is clear that the ambulatory adult found to have oil-aspiration pneumonitis is promptly told to discontinue taking mineral oil. As indicated above, early lipid pneumonia changes will ultimately resolve if this source of lung irritation is stopped in time and if there is no neurologic or anatomic defect in the nasopharynx, promoting additional insults to the already damaged pulmonary tissue. Occasionally, a Zenker diverticulum will be found acting as a reservoir for the spilling over of oil into the lower respiratory tract.¹⁷ This should be appropriately treated.

If there is superimposed pulmonary suppuration or bronchiectasis, the treatment may well be the surgical extirpation of the involved lobe or lobes in patients who are good surgical risks. Lobectomy may also be a wise procedure when a patient with proved oil pneumonitis suffers recurrent attacks of acute bronchopneumonia on top of a one-sided

lesion whose likelihood of clearing up after the discontinuance of the oil habit is remote. A less common indication for radical treatment is the concurrent or possibly subsequent development of alveolar cell carcinoma.¹⁸

CASE REPORTS

The following is a brief presentation of 5 cases of oil-aspiration pneumonitis with the pertinent clinicoroentgenologic data. Curiously enough, all patients were men in their sixties, 4 cases may be said to have been picked up on survey chest films, and the benign course of 3 cases has been followed for some time.

CASE 1. H. K., a 67-year-old retired laundry-truck driver, had never had a chest x-ray examination until visited by a

FIGURE 3 Film Taken in Later Examination in Case 2

mobile survey unit in May, 1948. He had had a slight cough, which was often spasmodic for about 20 years. He expectorated a small amount of greenish, nonodorous sputum daily. There was no appreciable dyspnea on exertion or orthopnea. He was subject to infrequent colds associated with a slight fever lasting a few days once or twice a year. No weight change had been noted over the course of years. On the basis of fluoroscopic examinations recently performed, he was told by his physician that the lung changes noted were due to a failing heart.

He had been taking 2 or 3 tablespoonfuls of mineral oil almost daily for the relief of constipation for the past 25 years. He was in the habit of drinking the oil directly from the bottle, and took this medication during the day as well as before retiring. He did not use nose drops. He did not gag or choke when taking anything by mouth.

Physical examination on June 29 disclosed a patient who did not appear acutely or chronically ill. There was moderate clubbing of the fingers and some cyanosis. No cardiac abnormalities were found. Examination of the chest revealed diminished breathing at the right base, no rales were heard. The gag reflex could hardly be elicited.

in the extent of the lesion under these circumstances is usually due to a subsiding acute pneumonitis superimposed upon the chronic process. Once the acute infection is over, the proliferative lung disease will continue its very slow progress. With the discontinuance of this type of laxative habit, early infiltrations have been seen to clear up. How-

FIGURE 1 Roentgenogram in Case 1

ever, the large lesions change little radiographically for years after oil aspiration has ceased.

DIAGNOSIS

Until now the diagnosis of lipid pneumonia has been too frequently a pathological one. In view of the experience presented below, more of these cases will undoubtedly be uncovered by case-finding surveys. With the extension of chest screening to general-hospital admissions, still more cases of oil-aspiration pneumonitis with few symptoms should be uncovered if the index of suspicion of this phenomenon runs high. The importance of making the diagnosis cannot be too strongly stressed, among other reasons, lest a case of this sort be sent to the surgeon for needless lobectomy or pneumonectomy.

A history of regular ingestion of mineral oil should be inquired into when one is dealing with a basal process of undetermined etiology in an otherwise well adult. Certainly, the suspicion of chronic benign pneumonitis due to liquid petrolatum must be seriously considered in the presence of a bilateral lower-lobe process found on a routine chest film of an adult who has few respiratory complaints and

who exhibits few physical signs on examination of the thorax.

The chief difficulty in differential diagnosis occurs when the lesion is unilateral. Then the possibility of neoplasm is uppermost in the mind of the present-day clinician. Contrary to bronchogenic carcinoma, however, in this chronic benign process the x-ray film reveals the lesion to extend peripherally, atelectatic phenomena are absent, and hilar adenopathy is not usually seen. Although carcinoma of the lower respiratory tract can exist with relatively few symptoms referable to the lungs, the cause of the process is less likely to be neoplasm than oil-aspiration pneumonitis, in which negative bronchoscopy is the rule unless there has been supervening infection.

The differentiation of lipid pneumonia in the adult from basal tuberculosis, primary bronchiec-

FIGURE 2 Routine Film of the Chest Taken on June 10, 1944, in Case 2, Showing an Ill-Defined Infiltration Under and Adjacent to the Left Heart Border and Also an Old, Minimal Lesion at the Right Apex

tasis or mycotic bronchopulmonary infection is a less difficult task. In these ailments, the symptoms, signs and difference in x-ray shadows are usually in sharp contrast to those of oil-aspiration pneumonitis. In addition, the examination of the sputum for specific organisms and the character and quantity of the expectoration will clinch the diagnosis of these chronic infections.

Two certain confirmatory tests have been used in the diagnosis. Both are based on the pathological finding that mineral oil remains in the alveoli long after aspiration into the affected lung has ceased.

may be that he invariably went to sleep on his left side shortly after taking his usual nightcap of mineral oil

CASE 3 S D, a 60-year-old Negro porter, first came under observation when given a routine x-ray examination in an effort to trace the possible source case to his son, who had died of pulmonary tuberculosis in January, 1948

The patient had no cough or other respiratory symptoms. His appetite had been good. His occupation had always been that of porter. There had been no exposure to noxious dusts. He had not been using nose drops. For the past three winters he had been in the habit of taking a tablespoonful of mineral oil daily after breakfast. He had also been taking this hydrocarbon at infrequent intervals in the other seasons of the year.

Physical examination disclosed no abnormal findings except for slight malnutrition and a markedly diminished gag reflex. The sputum was negative for tubercle bacilli and positive for oil droplets grossly and microscopically. X-ray study of the chest on May 17, 1948, showed a fine nodular lesion in the left-lower-lung field anteriorly between the level of the fourth and sixth ribs (Fig 4). The appearance of the process was not unlike that seen some time after bronchoscopy when incompletely expectorated iodized oil has been left in a number of the alveoli.

The interesting feature of this case is that it probably represented an early completely asymptomatic oil-aspiration pneumonitis. Much less of the hydrocarbon had been aspirated into the lungs in this case than in the previous ones. All that is needed here is the prompt recognition of the cause of the pulmonary lesion and asking the patient to desist from taking any more mineral oil. In view of the paucity of the pulmonary reaction there is a likelihood that the left-lung lesion will become reversible to a great extent after some time once the oil ingestion habit has ceased.

Unfortunately, the recovery of oil in the sputum or by lung puncture in the following 2 cases could not be obtained, owing to nonco-operation. However, the clinicorontgenologic course, the history and the very long follow-up study have left no doubt in my mind, or in those of many groups of radiologists and phthisiologists to whom the films have been shown, that these are also excellent examples of insidiously developing pulmonary granulomas due to chronic aspiration of mineral oil taken for laxative purposes.

CASE 4* H S, a 63-year-old real-estate operator, had been followed for 2 years since the discontinuance of the mineral-oil habit.

The pulmonary lesions had been discovered in a case-finding survey, done on June 17, 1946. This film and an oblique view taken on the same day showed a large area of ground-glass density confined to the right middle lobe and a small, less well defined area of similar character in the left-lower-lobe region just above the diaphragm (Fig 5). A diagnosis of carcinoma of the lung was made elsewhere, and the patient was in a greatly wrought-up condition over the concern shown him because of the accidental findings in the chest film.

It was believed that the bilateral process spoke against carcinoma, as did also the almost complete absence of symptoms and signs and the apparent excellent preservation of health. An absent gag reflex was also noted.

On careful questioning the patient gave a history of taking mineral oil for constipation for the past 20 years. Hardly a day had passed, according to this patient, without his tak-

*This case has been reported elsewhere.¹¹

ing about 2 ounces of liquid petrolatum, which he often drank from the bottle. This preparation was consumed both day and night. He took no nose drops and had no dysphagia.

A film taken 2 years after the discontinuance of the mineral-oil habit showed no appreciable change in the extent or character of the pulmonary lesions that had been revealed on the original x-ray survey. His general health remained excellent.

The diffuse fibrosis characterizing this case of long-standing oil pneumonitis is obviously not reversible, as indicated by serial films taken over a two-year period. Nevertheless, since the patient discontinued taking liquid petrolatum his health has remained good, and he has had no intercurrent illnesses, respiratory or otherwise. Altogether, he has

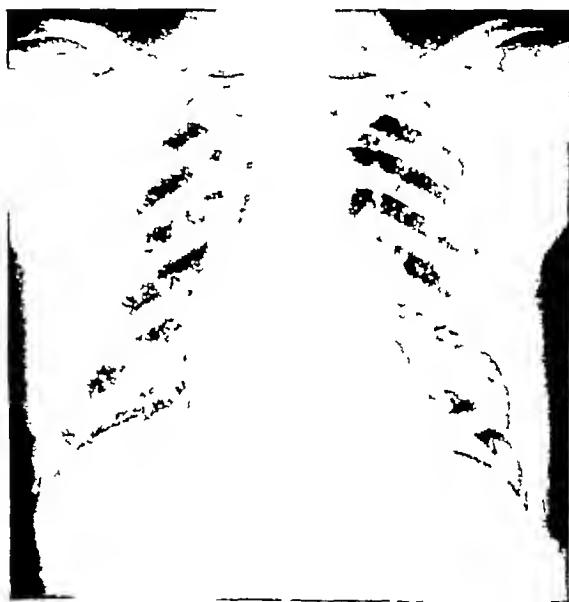

TABLE 6 Roentgenogram Taken on August 15, 1935, in Case 5

been none the worse for the mild disease of his own creation. He considered it therefore a cruel imposition to make him give up mineral oil of which he was fond beyond its laxative effect. Breaking this habit in time, however, may have saved him from more serious and enveloping lung changes in the future.

CASE 5 H C, a 60-year-old bookkeeper, was referred for bronchography because of obscure bilateral basal pulmonary lesions, more marked on the right side. He gave a history of repeated attacks of bronchopneumonia for the past 12 years. After an early one of these acute infections, a chest x-ray film on August 15, 1935, showed nothing more than heavily increased markings more prominent in the region of the left lower lobe than elsewhere (Fig 6). Numerous serial films since then had disclosed a slowly spreading right basal lesion, which was dense in its lower aspect and fluffy as it approached the normal portion of the lung above. In addition they revealed a less pronounced, spreading, infiltrative process at the left base (Fig 7).

In recent years the patient had noticed increasing dyspnea on exertion, some cough and expectoration and a slight obstruction to the passage of food in the upper throat. Many

X-ray study of the chest showed a diffuse conglomerate infiltration in the lower half of both lungs, denser and more marked on the right side (Fig 1). There was a suspicious area of central necrosis within the right basal lesion. On fluoroscopy both leaves of the diaphragm appeared smooth and moved freely. The right costophrenic sinus was obliterated.

Examination of the blood revealed a slight secondary polycythemia. The sputum was negative for tubercle bacilli. Some days after the ingestion of oil had been discontinued,

lesion at the right apex. No respiratory symptoms or lung signs were noted at that time. At a later admission during the summer of 1947 the patient complained of a slight cough, and a chest film showed a very large, uniformly dense and sharply circumscribed lesion (Fig 3) in the left-lower-lobe area, the infiltration in the lobe having coalesced and giving the appearance of a uniformly dense, discrete mass (parafinoma). A provisional diagnosis of bronchial neoplasm was made. Bronchoscopy showed only a thickened, congested and narrowed left bronchus, and a Papanicolaou smear of the sputum was negative.

When this patient was seen on a routine visit in April, 1948, the examiner was impressed with the fact that the left basal lesion had progressed only slightly on serial x-ray study since the preceding July. Furthermore, the patient looked too well and comfortable for a person ill with a bronchial carcinoma of that size of at least 1 year's duration. Close questioning disclosed that he had been taking 2 tablespoonfuls of mineral oil regularly at night for the previous 10 years. He was thereupon readmitted to the hospital for aspiration biopsy of the left lower lobe under fluoroscopic control, according to the method outlined above. He stood the procedure well, and there were no ill aftereffects. Free oil droplets were easily found in the fluid withdrawn from the lung on both gross and microscopical examination.

In this case the growth of the lipid-pneumonia lesion could be traced on the x-ray film from its

FIGURE 4 Roentgenogram in Case 3

the patient was asked to bring in some sputum for examination for liquid petrolatum, in accordance with the procedure outlined. The sputum was thick and greenish and had no odor. The presence of mineral-oil droplets was readily demonstrated microscopically.

This was probably a long-standing case of lipid pneumonia. Secondary suppuration was undoubtedly present, characterized by the expectoration of purulent sputum, the x-ray picture of the right base and the clubbing of the fingers. The typical distribution of the process in this ambulatory patient and the paucity of physical signs are worth noting, as is the ease with which mineral oil was found in the sputum.

CASE 2 E Y, a 64-year-old unemployed laborer, had had numerous hospital admissions for nondisabling rheumatoid arthritis and had recently developed arteriosclerotic heart disease with congestive failure. At present he was an ambulatory patient receiving weekly injections of mercurial diuretics and complained of nothing more than some dyspnea on exertion.

During one of his sojourns in the hospital a routine chest film done on June 10, 1944, revealed, in addition to the presence of a slightly enlarged heart, a scattered infiltrative process adjacent to the left cardiac border that appeared to be emerging from underneath the left side of the heart (Fig 2). There was also an old, minimal, fibrocalcific tuberculous

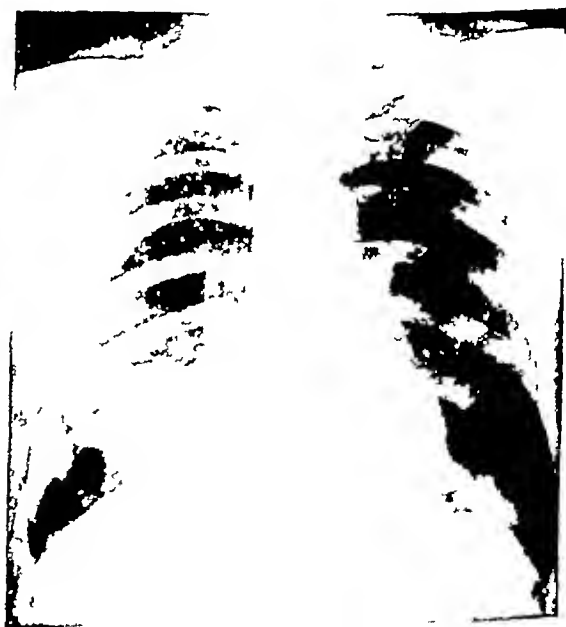

FIGURE 5 Roentgenogram in Case 4

The mesh-like fibrosis in the right middle lobe, as well as above the left leaf of the diaphragm, presents a different appearance from that in the previous cases

early beginnings as a nondescript basal infiltration to subsequent discrete tumor formation. The ease with which free oil was found on needle biopsy that helped clinch the diagnosis is also worth noting. If the disposition of the aspirated oil depends on gravity one expects the basal pneumonitis to be more likely on the right than the left side. A possible explanation for the fact that the pulmonary involvement was located exclusively on the left

of the pulmonary hazard to the habitual users of this bland laxative

Since this paper was submitted for publication, 2 additional cases of oil-aspiration pneumonitis in ambulatory adults who had been taking liquid petrolatum as a laxative for many years have been encountered, one was seen in consultation because of a history of repeated episodes of low-grade lower respiratory infections, and the other, picked up on survey, had a small, circumscribed lesion (paraffinoma) at the right base diagnosed as lung tumor preoperatively

COMPLICATIONS FOLLOWING PARAVERTEBRAL LUMBAR SYMPATHETIC BLOCK WITH NUPERCALINE IN OIL*

Report of a Case

JACOB T BRADSHER, JR, M D †

BOSTON

THE complications following the use of procaine and procaine-like compounds in producing therapeutic and diagnostic paravertebral lumbar sympathetic blocks are infrequently reported in the literature. However, the relation of the sympathetic chain to the spinal cord and the major vessels in much of its course, the relatively poorly controlled method of placing the anesthetic solution around the chain and the toxicity of the anesthetic agents used make the procedure occasionally hazardous.

Shumacker,¹ in his experiments with guinea pigs, found the median lethal dose of procaine (USP) when injected into the lumbar paravertebral area to be half the subcutaneous dose. He also reported 2 clinical cases of shock-like episodes following the use of procaine for paravertebral lumbar sympathetic block.² From his observations, Shumacker² believed that the aged tolerate local anesthetic agents less well than the young do.

Although the subarachnoid space was occasionally entered during use of the paravertebral sympathetic block before the case reported below, this has been easily recognized by the usual precautions and without ill effect. Entry into the subarachnoid space seems to be more common when the needle is directed cephalad.³ Adelman and Irwin⁴ reported 2 nonfatal cases of aseptic meningitis in young white men following paravertebral lumbar sympathetic blocks using 30 cc of 1 per cent procaine solution in each case. The spinal fluids

showed, respectively, 4000 and 3485 leukocytes, predominantly polymorphonuclears, per cubic millimeter. The spinal-fluid sugars were normal in both cases. Smears and cultures for organisms were negative. The meningitis was interpreted as being due to a chemical irritation produced by pyrogens in the distilled water of the solution used. Aseptic or chemical meningitis following spinal anesthesia was reported by Orkin⁵ as occurring in 0.26 per cent of 45,966 cases collected from the reports of twenty authors. Livingstone et al⁶ described 2 cases of chemical meningitis following spinal anesthesia and also reviewed 8 other case reports of the same complication. Of the 8 cases, 2 had followed the use of nupercaine, 4 procaine only, 1 procaine and epinephrine, and 1 procaine and strychnine. In this group there were 3 deaths: 1 after nupercaine, and 2 after procaine anesthesia.

The following is a case report describing complications without recovery after a paravertebral lumbar sympathetic block using nupercaine in oil.

CASE REPORT

N. R., an 87-year-old widower, entered the hospital on April 20, 1948. About 1 week prior to admission a small "infection" had developed over the first metatarsophalangeal joint of the right foot. Five days before admission he burned his foot with a hot bath. He gave no history of diabetes by name and symptoms.

The past history revealed occasional ankle edema for the past few years. The remainder of the history was irrelevant.

Physical examination showed a well preserved, small, alert and co-operative man who had a poor memory. The dorsum of the right foot was red, swollen and tender. At the base of the toes there was a linear, depressed, darkly crusted area measuring 5 by 2 cm. Overlying the first metatarsophalangeal joint on the right was an oval, blackish area over 0.5

*From the Fifth Surgical Service, Boston City Hospital.

†Assistant resident, Boston City Hospital.

radiologists and chest clinicians had seen him in the course of years, but no working diagnosis of the pulmonary lesion had been made. Bronchoscopy yielded negative results, as did sputum examinations. When he appeared for bronchography 12 years after the initial study, he gave a history of having taken mineral oil nightly in doses of about 1 ounce regularly for over 15 years. Instillation of iodized oil on July 12, 1947, showed distorted and obstructed bronchi in

FIGURE 7 Roentgenogram in Case 5 Taken Ten Years after That in Figure 6, Showing Upward and Conglomerate Progression of the Lesion

Note the very dense process on the right and the infiltrative lesion on the left

the region of both lower-lobe granulomas and the surprising accidental finding of a Zenker diverticulum (Fig 8)

This case is similar to the one reported by Tchertkoff,¹⁷ which subsequently came to autopsy and showed the typical findings of mineral-oil pneumonitis. The latest films demonstrated a more extensive involvement than that in any of the other patients described above. This is accounted for in part at least by the frequently superimposed pneumonias from which the patient suffered. Unfortunately for him, the cause of the basal pulmonary disease was not established till more than a decade after he came under observation. He has now ceased taking mineral oil for a year, the chest picture has remained unaltered, and his symptoms are practically unchanged. Operative removal of the Zenker diverticulum has been contemplated. The accidental finding of this pulsion diverticulum may be attributed to the fact that the bronchogram was done by the supraglottic route rather than via catheter.

SUMMARY

A typical clinicoroentgenologic picture occurring in some ambulatory older patients who have been habitually taking mineral oil for laxative purposes is described.

The gravitational distribution of the lesions and the paucity of symptoms and physical signs, at least in the early phases of this man-made disease, are emphasized.

It appears clear that it takes some time for a roentgenologically evident pulmonary reaction to this bland, liquid foreign body to develop.

Because of the age of these patients, if the lesion due to the aspiration of liquid petrolatum is one-sided, the common error is made of calling this benign disease a malignant neoplasm and subject-

FIGURE 8 Roentgenogram Taken on July 12, 1947, in Case 5, Showing Further Progression of the Lesion

ing the patient to needless lobectomy or pneumonectomy.

Because 3 of the 5 cases were picked up on tuberculosis case-finding surveys and because all 5 were seen within a two-year period, it is predicted that many more such cases will be discovered in older population groups if the index of suspicion of the disease remains high.

In view of this experience, a chest survey of well adults who take mineral oil for the relief of constipation is being undertaken to ascertain the extent

showed no change from normal until the day following injection when it became elevated. There were no marked changes in the character of the pulse, except for some increase in rate after the temperature began to rise. It seems safe to assume that the phenol played no important part in the patient's reaction.

Benzyl alcohol (phenyl carbinol) is relatively nontoxic, being rapidly converted to hippuric acid in the body.⁹ It is irritating and somewhat corrosive as pure substance, but the watery solutions that contain up to 4 per cent are not. In all proportions it is soluble in oil and is somewhat antiseptic. In dogs spinal anesthesia has been produced by 2 to 4 per cent solutions in saline or oil.¹⁰ Aqueous solutions have only brief anesthetic action, and the anesthesia produced is uncertain. It seems unlikely that, except for some possible transient anesthesia and a questionable irritation of the leptomeninges, the benzyl alcohol was responsible for any of the symptoms presented in this case.

Oil of sweet almond (*oleum amygdalae expressum*) is one of the fixed fatty oils and considered nontoxic and nonirritating.¹¹ Lipiodol, which is iodized poppy-seed oil containing about 40 per cent iodine in organic combination, when injected intrathecally is said to cause a well marked transitory aseptic meningitis with symptoms of meningeal irritation.¹² Boyd¹³ states that degenerative changes in the gray matter and thrombosis of the vessels of the anterior horns may also occur. The oil of sweet almond may have been responsible for some of the cellular reaction seen in the spinal fluid.

Nupercaine is the most toxic of the commonly employed anesthetics, and on intravenous injection is six times as toxic as cocaine.¹⁴ Clinical toxicity, however, seems to depend upon the concentration, and the extreme dilutions used for spinal anesthesia result in very little evidence of toxicity. The dosages for spinal anesthesia vary between 6 and 10 mg. Nupercaine is more rapidly absorbed from the subarachnoid space than from any area (except after intravenous administration).¹⁵ The most prominent toxic effects of nupercaine are on the circulatory system and are more pronounced than those from any of the other commonly employed spinal anesthetics.¹⁶ Bieter et al.,¹⁷ experimenting with spinal anesthesia in rabbits, observed irritant or toxic symptoms with ocular complications, convulsions and spasticity of the head, neck and forelegs. Of the procaine and procaine-like compounds used, nupercaine and pantocaine (tetracaine hydrochloride, *USP*) showed the toxic effects most frequently. Davis and his associates,¹⁸ using nupercaine, procaine and similar compounds intrathecally in dogs, found the most constant change to be an aseptic meningeal reaction. For the most part, the exudates were of the lymphocytic type. The authors also observed degenerative changes in the spinal cord.

In the case reported above, the initial fall of blood pressure, with the pulse remaining at near normal levels, frequently seen with spinal anesthesia, was probably the result of absorption of nupercaine from the spinal canal. The response to the sympathomimetic agent is somewhat confirmatory. Since the level of anesthesia never rose above the umbilicus and there was no evidence of respiratory paralysis, it can be assumed that the later stupor and convulsive movements of the arms were systemic reactions to the nupercaine similar to the reactions described by Shumacker.² Control of the clonic movements by barbiturates favors this explanation. In view of the experiments of Davis,¹⁸ Orkin⁵ and Livingston,⁶ one is led to believe that the nupercaine was chiefly responsible for the meningeal reaction.

The increasing stupor and changes of respiration during the day before death probably were signs of increasing reaction.

SUMMARY

A case is reported of an elderly man who, having shown a good peripheral vascular response to two previous paravertebral lumbar sympathetic blocks, developed motor and sensory changes, circulatory depression, stupor, convulsive movements of the upper extremities and late signs of meningeal irritation with death after a third block, using nupercaine in oil. The nupercaine seemed to be the chief causative agent, with possible added effects of the phenol, benzyl alcohol and oil of sweet almond — other ingredients of the solution used.

cm in diameter. The dorsalis pedis and posterior tibial pulsations were faintly palpable bilaterally. The radial arteries were sclerotic and tortuous, with marked beading. The heart was normal except for an occasional premature systole. The chest was narrow, and a moderate dorsal kyphosis was present. The lung fields were clear to percussion and auscultation.

The temperature was 98.6°F, the pulse 84, and the respirations 20. The blood pressure was 156/88.

Examination of the blood revealed a hemoglobin of 80 per cent and a white-cell count of 8700. The urine had a specific gravity of 1.015, was free of sugar and showed a ++ reaction for albumin, and the sediment contained many white cells and a few white-cell casts. The nonprotein nitrogen was 34 mg per 100 cc. The fasting blood sugar level was 80 mg per 100 cc. The blood Hinton test was negative.

The patient was placed on bed rest and given intramuscular injections of penicillin. It was believed that hot wet packs to the foot and leg were indicated. After 1 day the condition of the foot seemed worse, and examination revealed that no dorsalis pedis or posterior tibial pulsations were palpable. The hot wet packs were discontinued, and moist boric dressings were instituted. The cellulitis subsided, but healing was slow. The first and second toes began to show some dark discoloration. It was decided to perform a right paravertebral lumbar block. The block was performed 5 days after entry according to the method of White and Smithwick,⁷ using 40 cc of 1 per cent procaine solution. The procedure was followed by improvement in the color and increase of temperature of the foot. Four days later a second block was performed. This time nupercaine in oil was used in an attempt to prolong the effect. A total of 10 cc of the solution was used, containing 50 mg of nupercaine. The improvement of the circulation to the foot was prolonged. On the 12th hospital day a third block was attempted. With the patient in the left lateral recumbent position, 20-gauge spinal needles were placed at the level of the first, second, third and fourth lumbar vertebrae. There was no evidence that the subarachnoid space had been entered, aspiration at each level yielding no spinal fluid. At each site 2.5 cc of nupercaine in oil was injected — a total of 10 cc (50 mg of nupercaine hydrochloride). Shortly after the injections the patient began complaining of "numbness" in both legs and then of inability to move either leg. A level of sensory anesthesia was identified just below the umbilicus. The patient was placed in the sitting position. There was no further rise in the level of the sensory anesthesia. Within a few minutes he complained of feeling faint, and he became pallid. The blood pressure dropped to 40 systolic, nearly 0 diastolic. The pulse was 90 and regular. The respirations remained slow and regular. Two minims of 0.5 per cent neosynephrin was given intravenously, with a resulting rise of the blood pressure to 220/120. Gradually the patient became somewhat stuporous, responding poorly. Nasal administration of oxygen was started. The blood pressure returned to 140/80. The pulse was 84. The blood pressure and pulse then remained stabilized. About 40 minutes after the injection of the nupercaine, the patient developed clonic movements of the upper extremities, which were relieved by the intravenous administration of 0.16 gm of sodium phenobarbital. The clonic movements recurred after 2 hours, and another 0.064 gm of sodium phenobarbital was given. Respirations were regular, varying between 20 and 24.

On the following day the patient remained drowsy and rather disoriented, this was thought to be largely due to the barbiturates that he had received. Motion and sensations returned to the left leg, but there was still a motor paralysis and anesthesia of the right leg. The blood pressure and pulse remained normal. The temperature rose to 101°F. Two days after the paravertebral lumbar injection the patient became quite stuporous and could be roused only by painful stimuli. The temperature rose no higher than 100°F, but the pulse ranged between 100 and 110. On the 4th day after injection the patient continued in a stuporous state. The temperature rose to 101°F by axilla. He was maintained on intravenous fluids and had a urinary output of 2000 cc in 24 hours. The nonprotein nitrogen on this day was 70 mg per 100 cc. It was noted that cervical rigidity had developed and that he winced when the neck was flexed. He moved both extremities at this time. Other findings were flattening of the nasolabial fold on the right, no sensory response below the neck and absent

abdominal, patellar and calcaneal tendon reflexes. The Babinski response was present bilaterally.

A lumbar puncture was performed in the third interspace. The initial spinal-fluid pressure was equivalent to less than 50 mm of water. The fluid was cloudy yellow, had a faint odor of the nupercaine-in-oil solution (oil of sweet almond) and clotted on standing. There were 4060 white cells per cubic millimeter, of which 84 per cent were polymorphonuclear neutrophils and 16 per cent were lymphocytes. A stained smear of the fluid demonstrated no organisms. The protein content of the fluid was 800 mg per 100 cc. Insufficient quantity of fluid was obtained to determine the sugar content. Culture demonstrated no growth on blood agar. Twenty thousand units of penicillin was injected intratheca. One hundred thousand units of penicillin was given parenterally every 3 hours, and 5 gm of sulfadiazine was given intravenously in 3000 cc of fluid. The temperature rose to 104.6°F by rectum. The respirations became labored and shallow. At 7:30 a.m. on April 5 — 4 days after the last paravertebral lumbar injection — the patient died.

Permission for autopsy was obtained, but the body was removed from the hospital prematurely and post-mortem examination was not performed.

DISCUSSION

The agent used makes this case somewhat more complicated than those previously reported. Nupercaine in oil is dispensed in 5-cc vials, a solution of 0.5 per cent nupercaine (25 mg), 1 per cent phenol (50 mg) and 10 per cent benzyl alcohol (0.5 cc) in oil of sweet almond. This preparation is primarily prepared for use in proctologic surgery. The benzyl alcohol and phenol have antipruritic properties, and the phenol also probably aids in reducing the surface tension. Previously, no difficulty with the solution had been encountered in this hospital. One "collapse" reaction, which occurred after a lumbar block, was done with 1 per cent procaine solution in physiologic saline solution.

No reports of the results of injection of phenol into the spinal canal are available. The toxic dose, orally, is given as 8 to 15 gm.⁸ Phenol is a general protoplasmic poison. In toxic amounts it is responsible for shock following widespread capillary damage. The blood pressure falls as a result of central vasomotor depression, but more because of the direct toxic action on the myocardium and finer blood vessels. Cold sweating is prominent, the urine is scanty and contains albumin and casts. Death results from respiratory failure, usually within twenty-four hours. The body temperature falls markedly. In man little central stimulation is observed, and the prominent effects are those of central depression.

The amount of phenol injected in this case would be no more than enough to act as a local anesthetic and irritant. Of the total of 10 cc of solution used, containing 100 mg of phenol, only a small amount probably entered the subarachnoid space. The marked fall in blood pressure that occurred responded quickly to neosynephrin, indicating no widespread injury to the capillaries or finer vessels. Sweating was not seen. Respirations remained regular until four days after the injection. The temperature

seen on culdoscopic examination. The fimbriated end looks as though it were closed by very delicate adhesions that extend outward to the broad ligament and the ovary. The left tube appears essentially the same except that the fimbria are tufted, and apparently open. There are a few adhesions leading from the fimbriated end outward to the broad ligament.

When a cannula is inserted into the uterine cavity, gas apparently does not pass at a pressure under 200 mm of mercury, at 200 mm there is a very slow leak somewhere, with no audible sound at the external os. Possibly, the left tube is patent at high pressure.

DISCUSSION

This patient presented no evidence of tuberculosis other than in the endometrium. It is impossible to say that the disease did not exist elsewhere, particularly in the tubes. Pottenger¹ states that tuberculosis of the uterus is almost always secondary to tuberculosis elsewhere in the body, usually the tubes, and Norris² that the tubes are invariably involved, but most authors give 85 to 90 per cent as the figure.

Data in the literature on the incidence of tuberculosis of the genital tract vary remarkably. Jameson³ gives a table of autopsy findings in women dying of pulmonary tuberculosis. Nineteen authors are quoted, and their figures vary from 1 to 30 per cent, with an average of 9 per cent involvement of the genital organs.

Eichner, Bookatz and Hirsch⁴ found gynecologic tuberculosis in 32 cases when they reviewed 1600 autopsies and 38,000 surgical specimens. They did not state whether these patients had tuberculosis elsewhere except to mention a case of tuberculous meningitis and one with kidney involvement.

In association with sterility, the incidence is apparently higher. Rabau, Halbrecht and Casper⁵ diagnosed tuberculous endometritis by strip curettage in 20 out of 208 sterile women, none of whom had evidence of tuberculosis elsewhere. Vogt (cited by Jameson³) found it in 7 per cent of 212 sterile women, and Jensen and McDonald⁶ in 8 per cent of 25 sterile women. Rock,⁷ at the Free Hospital for Women, Brookline, Massachusetts, observed only 12 cases in 2083 biopsies, an incidence of 0.6 per cent. It has been proved that pregnancy can occur and proceed to term in uteri that are the seat of tuber-

culosis, but Jameson³ believes that the figures regarding sterility in some reported series of genital tuberculosis are not reliable (as low as 17 per cent), in that the pregnancies had probably occurred before the disease was present.

The treatment of genital tuberculosis hitherto has been primarily surgical, although there have been many proponents of x-ray therapy and other measures.

Jameson³ reviews the various forms of treatment and cites a "salvage" of 72 per cent after radical surgery. Te Linde⁸ gives the same figures for "salvage," with a primary mortality of 7 to 9 per cent and cites Greenberg as giving an 11 per cent mortality when there is tuberculous peritonitis, but 27 per cent when only the genital organs are involved. According to Jameson,³ the results of medical treatment, x-ray therapy or conservative surgery are even less satisfactory.

SUMMARY

A case of endometrial tuberculosis is presented in which the disease was apparently arrested by streptomycin therapy.

Data from the literature indicate that tuberculosis of the female reproductive organs is not an uncommon cause of sterility.

Although radical surgery is at present the treatment of choice, even when it cures the patient of the disease, it leaves her deprived of her reproductive functions, and often of her ovarian hormones.

It is suggested that further trial of streptomycin therapy in endometrial tuberculosis is warranted.

STREPTOMYCIN IN THE THERAPY OF TUBERCULOSIS OF THE ENDOMETRIUM*

ALBERT ARANSON, M D,† AND RICHARD W DWIGHT, M D‡

FRAMINGHAM, MASSACHUSETTS

THE apparent arrest of endometrial tuberculosis consequent to treatment with streptomycin, hitherto unreported, appears to warrant the report of the following case

CASE REPORT

C L (CVAH 10,137), a 26-year-old married woman, was referred to Cushing Veterans Administration Hospital by Dr John Rock on November 20, 1947, for the treatment of tuberculous endometritis. She had been well until 1942, when she noted that her menstrual periods, which previously had lasted 4 or 5 days, were prolonged to 8 or 9 days. The flow was not excessive, and the cycle of about 30 days remained unchanged. She also began to have a white, non-odorous vaginal discharge. In April, 1944, she was married. At about this time she began to have vague cramps in both lower quadrants of the abdomen. These occurred irregularly, were not related to her periods and were not sufficiently severe to interfere with her activities. All these symptoms persisted without change until admission. In addition, during the 2 years prior to admission a vesicular rash had appeared on the shoulders at the time of her periods, and she had lost 20 pounds in weight during that time. Late in 1945 she consulted an obstetrician because of her failure to conceive. No cause was found. In July, 1947, she consulted Dr Rock because of sterility. An endometrial biopsy revealed tuberculosis of the endometrium. A second biopsy in September was identical, and she was referred for treatment with streptomycin.

The past history was essentially noncontributory. The patient had had the usual childhood diseases and, in 1939, typhoid fever. There had been no other serious illnesses, and no operations. She had always lived in the eastern part of the United States, and until 1941 in a region where the milk was not pasteurized.

Both parents were living and well. There were no dead siblings and no family history of tuberculosis or history of exposure to it.

She had worked as an accountant prior to service in the WAVES from February, 1943, to January, 1946, and again was working as an accountant.

Physical examination showed a somewhat underdeveloped and undernourished, intelligent, co-operative woman, in no distress. The weight was 130 pounds. The temperature was 98.6°F. The head, neck, eyes and ears were not remarkable, the tonsils were present, but were not inflamed. The teeth were in good condition. The chest was symmetrical, with normal expansion, and the lungs were clear to percussion and auscultation. The abdomen was normal on inspection and palpation, the back and extremities showed no abnormalities. The reflexes were physiologic. There was no enlargement of the lymph nodes. Pelvic examination showed a normal marital introitus, the uterus was normal in size and position, the left ovary palpable but not enlarged, and the right ovary not felt, there were no masses. The cervix appeared normal, there was a moderate amount of slightly frothy yellow vaginal discharge. Rectal examination was negative.

Examination of the urine revealed a trace of albumin on one of twelve examinations but was otherwise negative. The nonprotein nitrogen was 21 mg per 100 cc. The blood Kahn reaction was negative. The red-cell count was 4,100,000, with a hemoglobin of 11.2 gm, and the white-cell count 7900, with 52 per cent segmented neutrophils, 4 per cent band forms, 34 per cent lymphocytes, 8 per cent monocytes and

2 per cent eosinophils, the red cells and platelets were normal in appearance. During the hospital course the hemoglobin ranged from 11.2 to 12.2 gm, the white-cell count between 4100 and 7900, and the hematocrit from 38 to 40 per cent.

Several smears and cultures of the vaginal discharge were negative for acid-fast bacilli, a smear for trichomonas was also negative. An audiogram before treatment was within normal limits. Three x-ray examinations of the chest showed no abnormality.

The tissue section of the endometrial biopsy taken in September was obtained. The report was as follows:

Scattered small tubercles are found, with Langhans' giant cells present. The glands possess a few small papillary projections. The nuclei are predominantly basal. There is slight mucous production. Scattered mitotic figures are observed. There are degenerated neutrophils within the glands. Occasional groups of lymphocytes are seen in the stroma. The pathological diagnosis is tuberculosis of the endometrium.

On November 29 streptomycin therapy, consisting of 0.5 gm intramuscularly every 12 hours, was begun. This was continued for 129 days. There were no untoward symptoms. Audiograms made at 2-week intervals and at the end of treatment showed no loss of hearing. The patient remained in bed except for 1 hour each day. Streptomycin blood levels were determined every 2 weeks. The level was consistently 32 or 64 units per cubic centimeter, except on two occasions when it was 8 and 16 units. Except for a single evening temperature of 100°F, the patient was afebrile. Eosinophil counts during treatment were 2, 2, 11, 9, 3, 3 and 3 per cent. The sedimentation rate was 19, 14 and 20 mm per hour on three examinations.

The vaginal discharge diminished in amount. Three menstrual periods showed the prolonged flow experienced before treatment.

On March 22, 1948, pelvic examination under anesthesia was essentially the same as on admission. The uterus was normal in size and position. The cervix was dilated with ease, the cavity measuring 7 cm deep, smooth and symmetrical. A moderate amount of normal-appearing endometrium was obtained by curettage. One strip of endometrium was used for guinea-pig injection. The animal was killed on May 13, there was no evidence of tuberculosis.

Microscopical examination of the endometrium revealed straight glands with basal nuclei. There was little production of mucus. No tubercles were found, and there was no inflammatory exudate. The diagnosis was normal endometrium, proliferative phase.

The patient was discharged on April 2 and returned on June 1. She had been well and had resumed her work. There had been two menstrual periods with normal flow of 4 or 5 days, the last one on May 14. Dilatation and curettage was performed on June 2. The findings were the same as before, the pathological report showing normal secretory endometrium, with no evidence of tuberculosis. A cervical biopsy was also negative. One piece of endometrium was used for guinea-pig injection. The animal was killed on July 15, and showed no evidence of disease.

The patient was returned to Dr Rock for further study from the point of view of sterility. The following is a condensation of his report of a culdoscopy and insufflation done on July 24:

The fundus is visualized over part of the posterior wall, and part of the summit, and appears normal. Both ovaries are apparently no adhesions around the uterus. Both ovaries are partly adherent to the broad ligament, but otherwise appear normal. The right tube looks normal, and is seen throughout its length. It varies somewhat in thickness, but not to an unusual degree. The color varies from red to reddish yellow, but this variation is also quite commonly

*From the Medical and Surgical Services, Cushing Veterans Administration Hospital.

†Formerly chief Tuberculosis Section Medical Service, Cushing Veterans Administration Hospital.

‡Assistant chief Surgical Service, Cushing Veterans Administration Hospital.

contained mucopolysaccharides. The latter showed marked hydrolysis when exposed to hyaluronidase, indicating that they were hyaluronic acid. This suggests that pretibial myxedema results from a local disturbance of metabolism of mucopolysaccharides. These authors conclude that the presence of hyaluronidase in the normal thyroid gland and the recent discovery of an enzyme in the blood that destroys hyaluronidase furnish a basis for much speculation regarding the etiology of pretibial myxedema.

Ayres and Jensen¹⁰ report complete cure of the syndrome of otorhinophyma, pruritus and alopecia totalis with testosterone by mouth, 10 mg every one or two days for four months. The patient, a sixty-six-year-old man, had alopecia for fifteen years and later developed a generalized pruritic eruption, with inflammatory hypertrophy of the nose, ears, chin, cheeks and eyebrows, and with dystrophic nails.

After a careful study of the effect of x-ray therapy on rabbit testes, Callaway et al¹¹ conclude that scattered irradiation reaching the gonadal region of the patient receiving low-voltage therapy to the face or other more remote areas is negligible so far as injury to gonadal tissues is concerned.

Ephynal, a synthetic racemic alpha tocopheryl acetate, has been recommended for pruritus due to estrogen imbalance.¹²

Reporting on the spontaneous cure of tinea capitis in puberty, Rothman¹³ proves what has previously been only a theory. He shows that the reason for spontaneous cure in puberty and for adults' immunity to *Microsporum audouinii* infections is that with the onset of puberty the sebaceous glands of the scalp start to secrete a sebum that contains, in higher concentration than before, low-boiling saturated fatty acids with selective fungistatic and fungicidal action on *M. audouinii*. He demonstrates and identifies the low-boiling saturated fatty acids and the normal aliphatic monobasic acids with odd numbers of carbon atoms. The active fatty acids constitute a very small part of the total fat extracted, but such active acids have a minimum fungistatic concentration of 0.0005 per cent. These cures are effected slowly by the sterilization of the follicular canals and the surface of the scalp, preventing further spread, so that as the infected hairs are shed the infection disappears. This article is the result and report of a logical theory, which was tested by exact chemical procedures. Both the experiment and the article describing it are excellent.

The undermining of acne lesions by exteriorization is described by Bereston and Benteen.¹⁴ Treatment consists of excision of the acneiform area overlying the cyst or sinus beneath, healing is by granulation and occasionally grafting is indicated. The scarring of the surgical procedure is apt to be extremely disfiguring.

DERMATITIS AND ALLERGY

Klasson¹⁵ reports a study of ascorbic acid in the treatment of poison-oak dermatitis. He believes that vitamin C is capable of preventing and combating the disease. The best results were obtained for the most part in patients with edema of the eyelids and genitalia. This theory certainly needs substantiation. If verified, it would be a boon to outdoor workers.

Epstein¹⁶ adds another theory for the cause of localized bullous dermatitis or benign localized pemphigus — namely, focal infection. Such infection may be a factor in other cutaneous disturbances.

According to Steiner and Fishburn¹⁷ cutaneous eruptions from streptomycin occurred in 18.2 per cent of 33 patients, a marked contrast to 4.9 per cent of 1000 cases reported by Keefer. The temptation is strong to compare these reactions with "ninth-day erythema." Steiner comments that eosinophilia and "accelerated reaction time" on readministration of streptomycin point to the allergic nature of the reactions.

Dermatitis venenata due to streptomycin is frequently seen in nurses administering the drug.¹⁸

Zakon et al¹⁹ report 32 cases of lipstick cheilitis due to a bromfluorescein dye. All were cured by the substitution of lipsticks that contained no halogen derivative of fluorescein.

Discussing the treatment of diaper rash, Benson et al²⁰ recommend diapene (manufactured by Homemakers' Products Corporation), a quaternary ammonium compound (para di-isobutyl-cresoxy-ethoxy-ethyl di-methyl benzyl ammonium chloride monohydrate). Diaper rash is thought to be an ammonia dermatitis caused by decomposition of urea to free ammonia by *B. ammoniagenes* in the feces. Diapene inhibits *B. ammoniagenes* in vitro in dilutions of 1:200,000. Patch tests with 1:5000 dilution elicited no reactions. Of 50 cases treated, 49 were cured in a week, 1 case did not respond. There were 14 recurrences in two weeks after discontinuance of diapene, with a rapid response when it was used as a diaper rinse. These diapers should be a blessing to tired mothers. Diaper rash is a frequent occurrence and often resistant to treatment.

Robertson²¹ believes that the emotional background of a dermatitis may cause an acute exacerbation, and even resentment on the part of the patient. He presents a keen analysis of the patient's problems and the proper approach in directing their solution.

Forman²² reports that evipan narcosis offers a quick and probably reliable method of psychologic investigation that may be of value to the dermatologist for study on the basis of neurogenic cutaneous diseases.

MEDICAL PROGRESS

DERMATOLOGY

JOHN G. DOWNING, M.D.*

BOSTON

THE tremendous volume of papers on dermatology makes it impossible for the busy specialist to keep abreast of the literature. However, the establishment of the *International Abstract*, the *Quarterly Review of Dermatology and Syphilology* and the old favorite—the *Year Book of Dermatology and Syphilology*—lighten the burden. Many reports are repetitious, others are valueless. These reviews represent an attempt to separate the wheat from the chaff.

An excellent presentation of the skin manifestations of systemic disease has been written by Wiener,¹ who has coined the word "dermadrome" for such phenomena. The discovery of a systemic disease from a clue given by cutaneous lesions is very satisfying if the discovery prevents further extension of the disease, for example, the formation of small dark warty growths on the skin may lead to the early diagnosis of an operable intra-abdominal cancer, or bluish discoloration of the skin about the umbilicus may indicate rupture with an ectopic pregnancy.

In a study of the relation of acidity of the scalp to seborrhea, Cornbleet and Bergeim² found that the pH varied from 4.5 to 5.5, the acidity being chiefly due to lactic acid of sweat. Volatile acids were thought to be formed by the action of organisms on the lactic acid. These acids are believed to inhibit the growth of many micro-organisms and to cause itching when concentrated.

According to Lobitz and Mason,³ the palmar sweat glands, like the kidneys, seem able to form ammonia. Fifty-five specimens of sweat were collected from 5 normal men and 5 normal women and grouped in two physiologic types: profuse, 27 specimens, and intermittent, 28 specimens. Tests showed that the profuse palmar sweat had a lower concentration of ammonia nitrogen than the intermittent palmar sweat (7.7 and 28.9 mean, per 100 cc respectively).

In a comparison of sweat-gland response to direct heating and to reflex stimulation, Randall⁴ found that heat elicited profuse sweating by some glands, but the diffuse sweating that characterizes a reflex response was absent. There appears to be a threshold temperature, above which a direct response to local heat may occur and below which it does not occur. This critical temperature is several degrees above that necessary to induce sweating by reflex, when heat is applied to a large

area. Randall concludes that the profuse sweating response of individual glands to extreme temperatures is a direct one in contrast to the usual diffuse reflex response.

GENETICS

Whittle⁵ reports 2 cases of congenital poikiloderma, one in a twelve-year-old boy and the other in a four-year-old girl. There were areas of discoloration of the skin since birth, on the face, upper and lower extremities in one case and only on the cheeks in the other.

Acrokeratosis verruciformis (Hopf), a discrete keratoderma of the extremities, has a definite hereditary factor, as shown by Niedelman,⁶ who reports 4 males and 10 females of one family affected with this disease. Three males and 3 females in the same family were unaffected. This disease is differentiated from epidermodysplasia verruciformis, characterized by different types of verrucous lesions, by the fact that the histologic study reveals vacuolated cells in the latter. Niedelman questions whether this is sufficient to justify considering the diseases as different entities. He believes acrokeratosis verruciformis to be a hereditary nevroid dermatosis, possibly resulting from an inherited metabolic disturbance affecting normal utilization of vitamin A.

Porter et al.⁷ report 7 cases of Darier's disease (keratosis follicularis) in which 30,000 to 100,000 units of vitamin A were given daily for one to thirty months. There was great clinical improvement in 1 case, much improvement in another, little in 3 and no improvement in 2.

Hypertrichosis is frequently inherited. Reporting on electrolysis versus high-frequency currents in the treatment of hypertrichosis, Ellis⁸ states that electrolysis is slower but has less recurrences and rarely causes abscesses. Although the short-wave method is rapid, it has more recurrences and frequently causes abscesses and larger scars. Histologic study showed more severe damage to the epidermis resulted from diathermy, and most hairs recurred unless visible burns were produced, leaving scars. Destruction of the individual hairs either by electrolysis or high-frequency current is the only safe method of removing hair. I prefer electrolysis.

ENDOCRINES

Watson and Pearce⁹ chemically analyzed and tested against hyaluronidase biopsy specimens from 2 cases of pretibial myxedema and found that they

*Professor of dermatology and syphilology, Tufts College Medical School; professor of dermatology, Boston University School of Medicine.

demonstrated on isolated tissue or organs. The antagonism exerted peripherally could be modified by nervous or humoral influences in the intact animal.

A study was made of comparative anti-histaminic activity of six compounds by Winter.³⁵ He found that neoantergen caused fewer side reactions and that it was less toxic per effective dose than the other five compounds. Pyribenzamine was second in these qualities. Although these findings are claimed to be essentially in agreement with those of some investigators, they are at variance with others. Time will be required for proper evaluation of all these anti-histaminic drugs.

Halpern³⁶ did some experimental research on anti-histaminic drugs, thiodiphenylamine derivatives. Two derivatives designated "3015 R P" and "3277 R P" were reported to be less toxic and more active than the best previous anti-histaminic drug discovered by the French ("antergan").

Giving a detailed report on derivatives of N, N-dimethyl-N'-2-pyridyl-ethylenediamine as anti-histaminics, Litchfield and Adams³⁷ state that the substance was halogenated, producing two products tentatively named "chlorathen" and "bromathen," each of which is weight for weight twice as active and half as toxic acutely as pyribenzamine. Furthermore, it was noted that equal weights of either of these substances protect twice as long as pyribenzamine.

Henderson and Rose³⁸ report 64 per cent improvement in 138 allergic patients treated with pyribenzamine. Side effects in order of frequency were sleepiness, nervousness, nausea, dry mouth, vertigo, insomnia, headache and vomiting. Only 2 patients required discontinuance of the drug because of reactions. Pyribenzamine has been given for as long as a year without toxic effects. Its action, as well as that of benadryl, is temporary, and therefore a thorough search for the cause of allergy and its treatment remains necessary.

Urticaria due to sunlight is a distressing ailment. Ehrlich³⁹ showed by selective infiltration that the wave lengths of the offending rays lie between 3000 and 3750 Angström units. The patient was a thirty-five-year-old woman who for ten years had had urticaria on the areas exposed to sunlight. It is doubtful whether the positive transfer test in these cases is due to transfer of reagins (genuine allergy) or to a photosensitizing substance (a photodynamic phenomenon). Photosensitivity to sunlight from the use of sulfonamides is still an interesting problem. Watkinson and Hillis⁴⁰ report a study of a group of 470 soldiers receiving 2 gm of sulfanilamide daily for ten days as prophylaxis against epidemics of streptococcal sore throat. Vaccination for smallpox was given at the same time. Of 213 men receiving sulfanilamide after vaccination for smallpox, 49 per cent became photosensitive in one to ten days. These authors conclude that

the results support the hypothesis that drug reactions are due to liberation of toxins from a buried toxin focus, in these cases it was the vaccination with pustular stage that supplied the toxin.

Bradley⁴¹ reports a fatal case of periarteritis nodosa in a ten-year-old boy. The fact that this patient had had sulfonamides for otitis media at six years of age and was probably given the drug for three weeks prior to admission raises the question in her mind of the part played by sulfonamides and other drugs in the etiology of these diseases.

Rich and Gregory⁴² state that it is of interest that disseminated lupus erythematosus shows "sclerotic" coronary lesions of the same type as occur in rheumatic fever and periarteritis nodosa and in animals subjected to experimental serum sickness. These lesions, they state, must be related to lupus erythematosus, since they occur in children with that disease. Their work is well organized and controlled, and several good photographs support the statements.

In a report on erythema nodosum, Favour and Sosman⁴³ state that the concurrence of rheumatic fever and erythema nodosum is coincidental. However, both may be theoretically considered as hypersensitivity diseases. The multiplicity of unrelated infections and drugs known to initiate erythema nodosum has tended to obscure the role of the beta-hemolytic streptococcus. They state that mild secondary anemia, cervical adenopathy and occasionally enlarged hilar or bronchial lymph nodes characterized the illness, individual predisposition, a variety of infections and chemical agents and local trauma contributed to its occurrence.

Naide⁴⁴ gives an interesting discussion of allergic lesions following thrombophlebitis. Venous thrombosis may cause trapping of an allergen to bring out a subclinical allergic state or to accentuate a pre-existing allergic lesion, stasis dermatitis or eczema results. Trauma causes outpouring of these concentrated allergens into the area as demonstrated experimentally in a sensitized rabbit in which the traumatized ear became gangrenous after injection of the allergen, the noninjured ear being unaffected. This creates a vicious circle that causes chronic ulcers. Naide concludes by warning against the use of sensitizing drugs or even adhesive tape in these areas of stasis. Sensitizing drugs such as benzocaine, nupercaine, penicillin, mercury, resorcin and the nitrofurans should not be used in the treatment of a stasis dermatitis or eczema.

Reporting on intradermal tests with dirofilaria immitis extract in human filariasis, Zeligs⁴⁵ states that the test is of some value but that it cannot be depended on exclusively. It gives too many false-positive and false-negative readings to be dependable.

Young and Yeager⁴⁶ report 2 interesting cases of cyanosis secondary to the wearing of ink-stained athletic shirts. Two students practicing football

Owing to the ease of application, a new device, zippered elastic stockings, should be of value in the treatment of stasis dermatitides²³

Pfeiffer and Williams²⁴ think that a suspension of paraldehyde is a valuable sedative for patients suffering from pruritus. Its taste being obnoxious, it is disguised in the following prescription

SUBSTANCE	AMOUNT
Paraldehyde (U S P)	50
Powdered gum tragacanth	2
Glycyrrhiza syrup (as needed)	120
Make a suspension, shake before using 4 cc in ice water	

Combes²⁵ recommends a new tar preparation, zetar, but does not give its composition. Pure coal tar direct from the gasworks is an inexpensive and efficient preparation for the treatment of persistent cutaneous diseases. No matter how its derivative is incorporated in a compound, it helps a given number of patients, but sensitizes others.

Sharlit²⁶ does not believe that the alkalinity of toilet soap is dangerous for the skin. Nineteen samples of face powders bought at random were suspended overnight in water and the pH determined, all were on the alkaline side. He states that the fact that frequently used alkaline face powders do not cause damage to the face suggests that the damage from toilet soaps is exaggerated. He apparently disregards the difference in the methods of applying these substances.

Ellis²⁷ has reported 9 cases of allergic contact dermatitis due to wool fat and cholesterol.

By patch tests Lane and Blank²⁸ found that fatty acids of low molecular weight (lauric and oleic) were more irritating than those of high molecular weight. Among fatty acids present in soap in appreciable amounts, lauric and oleic acid gave more positive reactions. Patch tests of patients with chronic recurrent vesicular eruptions of the hands confirmed the foregoing observations. The authors state that sulfated oleic acid depends on the degree of sulfation for its irritation of the skin. If highly sulfated and combined with palmitic and stearic acids in a soap (dermolate), it is practically nonirritating.

I have followed with great interest the progress of the appearance of synthetic detergents during the last decade. The recent war, with its attendant shortages, gave them a tremendous impetus. The literature has been most misleading. Industrialists have installed expensive receptacles to supply these so-called nonirritant soap substitutes to the workers. Patients with erupted skins have been advised that they can use the detergents with impunity. It is my opinion that they are of little or no value and are much overrated, being promoted, as some brands of cigarettes are, through a few well chosen papers by nonmedical research

workers supported by grants given to large clinics. I have tested them on normal and diseased skins and found them wanting. I prefer the soaps from natural oils for normal skins and soothing vegetable oils for inflamed skins.

Apparently there will always be a skin perverse enough to do the unexpected—for example, to become sensitized to an anti-histamine drug. A case is reported of an eczematoid dermatitis of the hands, chest and thighs appearing after the use of pyribenzamine to prevent recurrent colds. With cessation of the dermatitis, repetition of ingestion of the drug caused a recurrence²⁹. This type of reaction challenges the histamine-release theory of allergic dermatoses.

Lowell³⁰ states that the understanding of allergic reactions remains incomplete. The difficulty lies in the absence of a direct means of investigating the conditions. Apparently it is the cell itself that is sensitized, and this is why these drugs have been of so little value in contact dermatitides.

Whittemore and DeGora³¹ report a successful passive transfer to sulfadiazine twenty-five days after an acute episode. Ten minutes after a dose of 0.5 gm of the drug (which had been taken a month previously for treatment of furunculosis), the patient had a cutaneous reaction consisting of itching, flushing and large wheals.

Frazier and Small³² present a thorough consideration of the immunologic and biochemical implications of allergic dermatitis. Their rational and inquiring discussion covers the question whether drug reactions are due to sensitization or toxicity and operate directly or by tissue combination. The authors believe that the disturbance in lipid metabolism that occurs in this disease should be investigated.

Aminophyllin (0.5 gm in 20 cc of fluid given intramuscularly) was tried by Epstein³³ in 17 cases of pruritic eruptions. Seven patients had dramatic relief in three to forty-five minutes, with no recurrence for twelve to thirty-six hours. One patient with eczema obtained relief for six days. Two patients were relieved, and subsequent injections controlled recurrences. Three patients with eczema, 2 with generalized pruritus and 1 with urticaria experienced no relief. Three patients obtained mild benefit, and 1 failed to return. It was noted that the local and general reactions were too severe for general use of this drug as an anti-pruritic agent. The injections require care in preparation, are very painful, with soreness persisting for days, and cause nausea. One patient nearly died from shock, and another menstruated for fifteen minutes after each of six injections. In this therapy, the cure is worse than the disease.

Loew³⁴ states that the major action of anti-histamine drugs is probably exerted directly on the peripheral effector cells that respond to histamine, since antagonism has frequently been

Occupational cutaneous cancer in England is discussed by Henry⁵⁶ in a detailed statistical report that describes the nature of the cancer's beginning, sites of predilection and progress. Workmen's compensation for epitheliomas in chimneysweeps or workers in pitch, tar or tarry compounds was first allowed in 1907. In 1914 it was enlarged to include cancer from mineral oil, bitumen and paraffin or their derivatives. Cancer resulting from arsenic has been a notifiable disease since 1896.

Schwartz⁵⁷ describes occupational pigmentary changes in the skin. They consist of excess of melanin and melanoid, metallic substances deposited in the skin (tattooing) and staining from external or ingested dye. Occupational causes of unusual formation of pigment in the skin are excessive exposures to actinic rays, coal tar, crude petroleum and residues of distillation, and asphalt. The last three are photosensitizers. Depigmentation results from injuries, from skin infections and from monobenzyl ether of hydroquinone, the anti-oxidant in rubber manufacture. The last is the only chemical reported to have caused occupational depigmentation without causing dermatitis. The action is not entirely clear.

According to Klauder and Brill,⁵⁸ the irritant action of petroleum solvents, like the defatting action, decreases as the boiling range increases. Petroleum solvents with boiling ranges up to and including that of kerosene are primary irritants. Beyond kerosene there is varying reaction from none to positive. In this report Negroes had the highest tolerance. Patients with dermatoses due to petroleum solvents had less tolerance than patients with those from other causes. Naphthenic kerosene gave more severe reactions than paraffinic kerosene of the same boiling point. Klauder and Brill conclude that petroleum-solvent dermatitis is a nonspecific sensitivity.

METABOLISM

In a paper on acne rosacea, Tulipan⁵⁹ states that telangiectasia, erythema, papules, pustules and hypertrophy are probably due to a deficiency of vitamin B complex, as a result of lack of intake or by faulty absorption. He cites a series of 96 cases whose response to treatment indicated that this deficiency is the primary cause of rosacea. Local treatment included an antiseptic and the following hydrophilic ointment:

SUBSTANCE	AMOUNT
Red oxide of mercury	0.075
Sulfur precipitate	15
Salicylic acid	10
"Quinolol compound ointment"	20
Aquaphor (as needed)	300

In my experience, local therapy with antiseptic compounds is a necessary adjunct to the internal

treatment of rosacea. Endocrine therapy in women seems to be of value.

Sachs et al.⁶⁰ give a brief but clear presentation of their ideas on a confusing dermatologic entity frequently mistaken for dermatophytosis, even by dermatologists. They suggest the name "acrodermatitis pustulosa perstans." Their report of 11 cases states that the eruption clinically may be identical with pustular bacterioid or pustular psoriasis. It persists for years and seldom remits entirely, beginning as a vesicle or pustule (sterile) on the palms, digits or soles, with predilection for the thenar portion of the palms and the center of the soles extending to the inner side of the feet. Treatment generally is ineffective. Occasionally, removal of a focus of infection or the internal administration of arsenic produces a cure.

Caro and Seneor⁶¹ consider a nonpustular psoriasis of the hands (with or without psoriasis elsewhere) to be more frequent than is generally believed. These lesions, usually seen on the extensors of the finger joints and knuckles, sides of the fingers, palms and fingertips, are bilateral but not always symmetric. A biopsy is often necessary for diagnosis. These cases are frequently mistaken for occupational eruptions.

Brunsting and Mason⁶² report further studies on porphyria, stating that pigmentation occurs in the acute form but that other cutaneous reactions are rare. In congenital porphyria, however, there is marked sensitivity to light, and in the chronic disease there are bullous eruptions after light exposure and the skin reacts to trauma in a manner similar to epidermolysis bullosa.

Dunsky et al.⁶³ report a normal-appearing newborn baby who at two months began to pass red urine. This continued, and the patient presented loss of fingernails and bullous lesions of the hand that resisted treatment, healing with pigmented scars. The teeth were purple brown, and there was pronounced generalized hypertrichosis. Splenomegaly occurred, and the skin became more fragile. The authors include a thorough report of the chemical study of the porphyrins.

Eosinophilic granuloma, despite its rarity, is still a popular subject for theoretical discussion. Thannhauser⁶⁴ believes that this entity is only a stage in a large syndrome, which might be entitled eosinophilic xanthomatous granuloma.

In a discussion of the syndrome of "burning feet" as a manifestation of nutritional deficiency, Glusman⁶⁵ states that burning feet were first described and attributed to dietary deficiency by the British in Burma in 1826. American prisoners in the Philippines from 1942 to 1945 were afflicted by the thousands, with or without other symptoms. The first symptoms were numbness, tingling and burning of the toes and soles. Later there were sharp shooting pains in the legs, usually bilateral and worse at night. In some severe cases there was

wore sweaters heavily numbered with Sanford's indelible ink, containing carbon black, phenol, ammonia, nigrozone and aniline oil. They developed generalized cyanosis with nervousness, vertigo and dyspnea, the symptoms subsiding in approximately twelve hours. In conclusion the authors state that indelible ink containing aniline oil will produce methemoglobinemia if allowed to remain in contact with the skin for a sufficient time.

A severe delayed reaction to penicillin is reported by Dolan.⁴⁷ The patient, a twenty-six-year-old man, gave a history of treatment with penicillin intramuscularly three years and two months previously. The ear canal was treated with penicillin, both orally and locally. Three days after treatment generalized pruritus and raised, erythematous areas, 1 to 6 cm in diameter, developed. Three days later the condition progressed to frank edema about the face and scalp, pitting edema of the ankles and feet, soreness of the buccal mucous membranes and pains in the muscles of the abdomen, back and extremities, with a temperature of 100.2°F.

Hopkins and Lawrence⁴⁸ state that sensitization from the local application of penicillin is not sufficient to prevent its subsequent parenteral use. They found sensitization severe enough to prevent or prohibit systemic treatment in less than 1 per cent of the cases.

Templeton et al.⁴⁹ state that penicillin contains two antigens—penicillin and its culture medium. Types of dermal reactions have been toxic, macular or scarlatiniform, occurring in the first few days after penicillin therapy was started, urticaria (most frequent and occurring seven to nine days after penicillin) and erythema multiforme and nodosum, bullous and lichenoid, which may occur a few hours after penicillin injection. Circulating antibodies were believed to occur on the basis of a modified Prausnitz-Küstner reaction.

According to Kiel,⁵⁰ pyoderma gangrenosum (ulceroneurotic skin lesions) and possibly the associated ulcerative colitis may be allergic reactions to bacterial infection elsewhere. She reports the case of a thirty-eight-year-old woman with an acute to chronic colitis of three years' duration, who suddenly developed many rapidly spreading, roughly symmetrical ulcers on the extremities and torso, with fever, hypoproteinemia and bone-marrow depression.

When gold compounds were injected in lethal doses into rats, BAL increased the survival time for all compounds studied—gold sodium thiosulfate, thioglucose and sodium succinidoaurate—with the exception of gold sodium thiomalate.⁵¹ In 2 cases observed BAL produced rapid amelioration of the acute signs of a dermatitis due to gold, but final healing of the eruption followed the usual course of a slow return of the skin to normalcy.

Application of the following prescription prior to exposure was successful in the prevention of mustard-gas burns.⁵²

SUBSTANCE	AMOUNT
Glycerol	50
Chloramine-T	18
Zinc oxide	50

Aldrich⁵³ treated 54 cases of pruritus ani and vulvae with undecylenic acid (2 per cent) in triethanolamine and zinc stearate in a water-miscible base—an emulsion. Fifty (88 per cent) were cured—that is, with no recurrences to the time of his report—in four to thirty-three days by the local application of this emulsion. Four cases were complete failures. Any such report needs confirmation. My experience in the treatment of pruritus ani and vulvae is at times disheartening.

OCCUPATIONAL DISEASES

Benedek⁵⁴ presents a differentiation between pompholyx and occupational dermatitis to remove confusion regarding the diagnosis and treatment of the latter. He claims that in 1925 he discovered *Bacillus endoparasiticus* to be the cause of pompholyx, and that this organism is constantly harbored in a location as yet unknown, frequently in the blood. It is his contention that if one gets a contact dermatitis at this time, the organism causes pompholyx in the injured skin, and cure is difficult or impossible without the use of an anti-endoparasitic vaccine. His ideas are in conflict with the present generally accepted concepts.

Hanzlik⁵⁵ studied the epidermal application of diethylene glycol monoethyl ether (carbitol). Carbitol and other glycols were rubbed on the skin of rabbits, in aqueous form or in ointment bases. Renal and liver damage (necrosis) were observed with toxic dosage, and this led to death. The order of toxicity was as follows: diethylene glycol was more toxic than ethylene glycol, technical carbitol, ethylene glycol and propylene glycol were more toxic than carbitol, and the LD₅₀ of carbitol was 0.32 cc to 0.08 cc per kilogram of body weight daily. The safe dosage is probably 0.04 to 0.02 cc per kilogram of body weight a day. Hanzlik's paper is a thorough investigation of a cosmetic and its industrial preparation. According to the Pure Food and Drug Administration, "any amount in excess of 5 per cent in preparations for topical application to small areas of the body would constitute a hazard." This study is of extreme value because of the use of carbitol and glycol in the formulas of various solutions and ointments containing medication. This toxicity must be considered when large amounts are used in large ulcers and sinuses over a long period.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

EDITH E. PARRIS, *Assistant Editor*

CASE 35081

PRESENTATION OF CASE

First admission A twenty-five-year-old single laborer entered the hospital because of varicose veins.

The patient was first seen in the Out-Patient Department three years previously for intermittent pain in both legs, occasionally associated with swelling. During the next three years he experienced occasional cramps in the legs and developed small, chronic, 1-cm ulcers above the medial malleoli. Physical examination was otherwise negative. A bilateral, long saphenous ligation was performed. The ulcers healed readily but about two months later reappeared.

Second admission He re-entered the hospital, where venograms indicated a blockage of the deep system. A bilateral lumbar sympathectomy was performed and dermatome grafts applied following excision of the leg ulcers. Positive blood Hinton and Wassermann tests were discovered, and he was discharged to the Out-Patient Department for treatment with mercurials and bismuth. The spinal-fluid serologic findings were negative. During the mercurial therapy he developed jaundice and albuminuria, and mercury was temporarily discontinued.

Third admission (five years later) During the interval the patient was seen periodically in the Out-Patient Department. The leg ulcers persisted without much change. The symptoms were improved, although he did not return to work. The day before this admission he had a hemoptysis (a cupful of bright-red blood). Physical examination revealed a nasal septal defect, distended pulsating neck veins, an enlarged heart, with a prolonged rough apical systolic murmur and accentuated pulmonic second sound, and generalized edema, particularly in the legs. The blood pressure was 110 systolic, 75 diastolic. A blood Hinton test was negative. The venous pressure was equivalent to 320 mm of water. The blood and urine examinations were negative. An x-ray film showed a heart enlarged in all directions. There was prominence of the pulmonary conus. The main branches of

the pulmonary artery were likewise dilated. There was no evidence of pleural fluid. The lung fields were not remarkable except for the dilated blood vessels. Fluoroscopy showed marked pulsation of the main pulmonary artery, but little pulsation of the hilar shadows. There was no enlargement of the left auricle, the aortic knob was almost absent.

An electrocardiogram showed right-axis deviation with evidence of right ventricular strain. The patient remained in the hospital about two months on a low-sodium diet, ammonium chloride and digitalis, during which he had a good diuresis. He had some paranoid and hallucinatory episodes.

Fourth admission (two and a half months later) He re-entered the hospital because of gradually increasing dyspnea and edema. In addition to the previous physical findings there was anasarca, a slightly enlarged liver and ascites. He remained in the hospital for three weeks under digitalis, mercupurin and urea treatment. The total serum protein varied between 5 and 6 gm per 100 cc, and the nonprotein nitrogen ranged from 25 to 60 mg per 100 cc.

Fifth admission (six months later) He was readmitted to the hospital because of an episode of hemoptysis. At this time he had massive edema. X-ray examination showed no evidence of intrapulmonary hemorrhage. Findings in the chest were much the same as those on last examination except for the transverse diameter of the heart, which was now 18 cm compared to 17 cm six months previously. An electrocardiogram showed auriculoventricular block, with findings consistent with chronic cor pulmonale.

Sixth admission (two years later) He was followed in the Out-Patient Department, with occasional exacerbation of the edema and treatment of the persistent leg ulcers. He re-entered the hospital with edema, more pronounced dyspnea, and complaining of yellow spots before his eyes. An electrocardiogram showed right-axis deviation and bigeminy. Digitalis was withheld temporarily, with disappearance of the bigeminy and the visual symptoms. During his hospitalization he exhibited several acute psychotic episodes with paranoid delusions. The total protein was 4.1 gm, and the nonprotein nitrogen 42 mg per 100 cc.

Seventh admission (four months later) At this admission he exhibited marked generalized edema. The total serum protein was 3.94 gm per 100 cc, with an albumin-globulin ratio of 1.1. The sodium was 129.9 milliequiv, the chloride 92 milliequiv, and the carbon dioxide 22.3 milliequiv per liter, the nonprotein nitrogen was 42 mg per 100 cc. An x-ray examination showed the heart to be slightly larger than on the previous examination, and there was definite evidence of fluid in each pleural cavity (Fig. 1). Some pulmonary edema was present, particularly in the left-upper-lung

involvement of the palms. Many patients had pelagra rashes, scrotal dermatitis, fissuring at the angles of the mouth, edema, diarrhea and so forth. These responded to nicotinic acid and riboflavin or B complex, whereas the burning feet persisted.

Lloyd and Williams⁶⁶ report a study of endocrine function in 71 patients with cirrhosis of the liver. Clinical endocrine changes observed in male patients consisted of decreased libido and potency, atrophy of the testicles, decreased body hair and gynecomastia. Telangiectasia and "liver palms" were also regarded as possibly being related to altered endocrine function. Decreased axillary hair was present in 46 of the 55 male patients (84 per cent).

An editorial in the *Journal of the American Medical Association*⁶⁷ states that "until clinical studies have been reported and critically analyzed, the local use of amino acids to accelerate wound healing can be considered only as an interesting observation."

(To be concluded)

the written report, especially as regards the density of the lung roots. Dr Wyman, would you discuss the films?

DR STANLEY M. WYMAN: As I understand from the record, these films begin and end in the last two-year period of the patient's illness and do not include the first admission. The most striking feature of the original examination is the markedly enlarged heart, the enlargement being more impressive toward the right than toward the left. In addition to that there was a very large main pulmonary artery. The aortic-knob shadow is lost in this region. I cannot identify it with certainty on any film so that it must be at most of normal caliber if not small. The vascular shadows extending into the lung at the right hilus are definitely more prominent than usual, and on the left there is still greater enlargement of the main branches. This prominence of the vascular pattern extends into the lung field, and I think possibly it is a little more pronounced in the left lung than in the right. I believe that the patient had on first admission a very small quantity of fluid in the right pleural space. The record in the X-ray Department stated that pulsations of the cardiac borders were of good amplitude, slow and regular. They described increased prominence of the amplitude of pulsation of the main pulmonary artery, but no hilar dance. They do not say whether or not absence of pulsations of the hilar arteries was ever observed. I think the lateral view shows the heart extending far upward along the sternal border, suggesting right ventricular enlargement, and there is a high pulmonary artery here arching in this fashion and in back of the main pulmonary artery a branch that is very large. There is just the faintest suggestion of the aortic arch above the pulmonary artery. As Dr Bland has pointed out, we did not think that the left auricle was enlarged.

The right anterior oblique view shows the trachea and the bifurcation of the main bronchi with a definite compression of the left main bronchus about 4 cm beyond its origin. I take this process to be due to unusual enlargement of the left main branch of the pulmonary artery. I cannot outline the diameter because I cannot separate it from the other overlying shadows. The other examinations were taken subsequently — these films were a year and four months after the original films and show the heart to be slightly larger and the vascular engorgement, if anything, to be slightly more pronounced. I agree with Dr Bland that I cannot be sure of the pulmonary edema described at one point in the left-upper-lung field. The film taken two years after the original films shows still further cardiac enlargement, and I think that the left hilar vascular shadow is increased still further and perhaps out of proportion to the increase in the right. There is a knob of density on the right just above the right main bronchus, which I believe is the

azygos vein. The best I can say on this is that the heart is enlarged, probably chiefly right ventricular and right auricular, with a huge main pulmonary artery and branches, particularly the left hilar branches, which seem to have increased in size out of proportion to the right.

DR BLAND: I would like to know the extent of pulsation in these hilar vessels beyond the main stems.

DR WYMAN: I do not know that.

DR BLAND: The implication is that it was present but not striking.

DR WYMAN: It certainly was not increased.

DR BLAND: You do not find evidence of old or recent infarcts?

DR WYMAN: No, we looked particularly for infarcts and we were unable to see any clear-cut evidence.

DR BLAND: This man bled a fair amount on several occasions. There was a statement in the record that there was no x-ray evidence of intrapulmonary bleeding. I cannot quite follow that.

DR WYMAN: I do not believe that by x-ray study one can say that a lesion in the lung is hemorrhagic unless asked a specific question and there is a good history to go with it. In the past we have seen hemorrhage lying peripherally in the lung field in a large circumscribed area, not having the distribution of infarct and having a homogeneous character with borders of poor definition. When lesions of this character have cleared up promptly we have assumed them to be hemorrhage. One such case discussed at one of these conferences perhaps a year ago, but not published, actually was removed surgically and proved to be hemorrhage.

DR BLAND: So the point is that you do not see anything that suggests a hematoma in the lung?

DR WYMAN: No.

DR BLAND: The first possibility that occurred to me in reading through the record was auricular septal defect. After seeing the films I am willing to discard that for several reasons. With auricular septal defect a tremendous volume of blood circulates around and around through the pulmonary system, and by cardiac catheterization it has been shown that the cardiac output with this defect is tremendous, at times up to 25 or 30 liters of blood, with only 3 or 4 liters going to the periphery. That indicates a great amount of blood circulating through the lungs. Under these circumstances the lung roots are massive. Therefore, I think we can safely discard that possibility after viewing the films.

What other congenital lesions should we consider that are noncyanotic at birth and yet may become slightly cyanotic later? One is the so-called Eisenmenger's complex, which is a modification of the tetralogy of Fallot. In this condition cyanosis usually appears in adolescence, and later with heart failure the patients are apt to be extremely blue. This does not quite fit the picture here. I cannot

field. He was discharged after about two weeks and remained at home for three weeks.

Final admission. He was admitted finally with generalized anasarca and gangrene of the right third and fourth toes.

He had loss of memory for recent events. There was pronounced venous distention in the neck. Both lung bases showed dullness to flatness, with diminished breath sounds and fine, moist crackles. The left cardiac border was percussed 3 cm. to the left of the midclavicular line. A Grade IV harsh systolic murmur was present, most marked near the apex. The pulmonic second sound was greater than

It is always annoying for the discussor to ask for something that is not available, and I am sure some one has spent many hours abstracting this long record, but before I start I really ought to know whether or not this man was cyanotic.

DR J H MEANS Yes, he was.

DR MORTON SWARTZ No, he was not cyanotic. That was one of the striking features.

DR TRACY B MALLORY There seems to be a discrepancy, but I think it varied on different entries. There are a number of comments that he was not cyanotic, and others that he was.

DR MEANS I would swear that I had seen him when he was at least somewhat cyanotic.

DR BLAND The original red-cell count might help.

DR MALLORY On the first admission there was a single red-cell count of 6,500,000, followed within a week by a count of 5,100,000 and one of 4,800,000. All subsequent counts were within normal range.

DR BLAND In any event we must explain this patient's pulmonary hypertension. The evidence is quite clear that that existed to an extreme degree. His main pulmonary artery was large and pulsating. He had a loud pulmonic second sound, and the heart failure was limited to the right side. Mitral stenosis is the commonest cause of pulmonary hypertension. He did not have mitral stenosis for several reasons. The lungs remained uncongested throughout his illness. This much heart failure secondary to mitral stenosis without congestion of the lungs could not exist. I question the statement of slight pulmonary edema on one occasion. There was no intracardiac calcification. That is not always present, however, with mitral stenosis. He had two years of heart failure and did not fibrillate. That would be most unusual if there were an important element of mitral stenosis. Besides, the X-ray Department said that the left auricle was not large. They make mistakes on that score, but nevertheless, I am certain that his pulmonary hypertension and heart failure were not due to rheumatic heart disease and mitral stenosis.

We are left with two broad possibilities. He had either some congenital lesion of the heart, which increased the amount of blood flow through the lungs, or something in the lungs in the pulmonary vascular bed, which gave him pulmonary hypertension. This morning I was told that it was all right to look at the x-ray films with the X-ray Department, and I urgently needed their help in this connection, especially to differentiate congenital defect from obstruction in the pulmonary circuit.

As to the presence of cyanosis, different opinions have been expressed. Most people with heart failure get a little dusky at times, but I think it is safe to assume that this patient was not constantly cyanotic. In viewing the films I was left with a different impression from that obtained from

FIGURE 1

the aortic second sound. The abdomen was tense, with pitting edema of the abdomen, flank dullness and a fluid wave.

The blood pressure was 110 systolic, 70 diastolic. Examination of the blood showed a hemoglobin of 10 gm. and a white-cell count of 17,650, with 90 per cent neutrophils.

Following admission the patient became more disoriented and had a hemoptysis (about 150 cc of bright-red blood). Although transferred to a psychiatric ward, his management became so difficult that transfer to a state sanatorium was necessary after about ten days.

He died about five days following the transfer.

DIFFERENTIAL DIAGNOSIS

DR EDWARD F BLAND When Dr Castleman asked me to discuss this case he said that I must have seen this patient at some time. He said that did not matter, however, the implication was evident. He even offered to let me abstract the record, but I thought that that might be too confusing so I did not do that. I have studied the x-ray films, however, with the X-ray Department.

DR BLAND That always comes up, and it is hard to answer. I do not know of any relation between the two. Do you, Dr Mallory?

DR MALLORY Buerger's disease has been claimed to involve the lungs. I do not know the evidence, however, and I have never seen it myself.

DR BLAND I think we can discard syphilis without serious thought.

DR WYMAN I wonder if Dr Bland attaches any significance to the apparent discrepancy in size of the two main hilar branches of the pulmonary artery.

DR BLAND That was fairly striking and is suggestive of unilateral thrombosis.

DR WYMAN The larger left hilar shadow is associated with apparently larger vessels throughout the left lung. It is very disturbing to make a diagnosis of thrombosis in the main pulmonary artery.

DR BLAND Unless it happened at this point (on the film).

DR WYMAN Yes, in back, and you cannot see it.

DR BLAND Is it fair to give Dr King a chance since this involves the lungs?

DR KING I had a similar case a year ago with phlebitis and varicose ulcers and cor pulmonale, and my guess was emboli, multiple small pulmonary emboli. I was wrong, it was primary vascular disease, so my inclinations here would be to make this primary chronic pulmonary vascular disease, as you have done.

DR MEANS Can I ask Dr King what kind of chronic pulmonary vascular disease?

DR KING I think it was called arteriosclerosis, if I remember correctly.

DR BLAND Dr Wyman wants to put a thrombus in the main right-pulmonary-artery stem behind the heart where it cannot be seen.

CLINICAL DIAGNOSIS

Cor pulmonale, cause undetermined

DR BLAND'S DIAGNOSES

Obliterative pulmonary-artery disease

Cor pulmonale

Congestive failure

Peripheral vascular disease (venous and arterial)

ANATOMICAL DIAGNOSES

Embolism and thrombosis of pulmonary-artery tree, diffuse, with organization and recanalization.

Cor pulmonale

Thromboangitis obliterans, leg vessels?

Ascites

Operative wound, old, lumbar sympathectomy, bilateral

PATHOLOGICAL DISCUSSION

DR MALLORY Autopsy showed a large thrombus in the main pulmonary artery, beginning 3 cm distal to the valve. It then extended to the bifurca-

tion and spread into both hilar arteries, completely occluding the one on the left and only partially occluding the one on the right. The cut surfaces of the lung parenchyma showed that all the vessels throughout both lungs were prominent and stiff and stood out from the surface. In many of them it was quite evident that the lumen had been at one time obliterated since small canalizing vessels were present within the larger ones. This process extended down to the most minute vessels in the lung.

In the upper right-hand corner of the microscopical slide can be seen a vessel that has been divided in two by a band of fibrous tissue, with two canalizing vessels on each side. In this next field is a vessel that has been divided into half a dozen different lumens by multiple fibrous septums. Here is a vessel with very marked intimal thickening and a single lumen, very much hypertrophied. Here are several extensively recanalized small vessels.

One is still left with the question of etiology of this process. It involves pulmonary arteries of all sizes from the main pulmonary artery down to the smallest arterioles — fairly uniformly distributed throughout both lungs. The changes all seem to be internal to the internal elastic lamina, there are no changes in the media of the vessels. They can all be explained on the basis of multiple pulmonary emboli with organization and recanalization, followed by a retrograde thrombosis going back into the main arteries. I do not see any way that I can prove that is the case. It is not very different from what has been described as primary endarteritis except that the multiplicity of the canalizing vessels is much more like organization of emboli.

DR GORDON S MYERS Was any source for emboli found?

DR MALLORY There was extensive disease of both arteries and veins in the legs, with almost complete obliteration of the left femoral artery about 6 cm below Poupert's ligament. None of the changes at the time of autopsy were characteristic of Buerger's disease, and the original biopsy, to my eye, was not characteristic either. The biopsy showed a large vein, which looked like a recanalized varicose vein and not particularly like Buerger's disease. But Buerger's disease is only specific in its histology for a brief period in the acute stages. In later, chronic stages one can only guess about it.

DR MYERS Did this disease involve the capillaries as well as the arterioles?

DR MALLORY It went as far as the smallest arterioles, but no capillaries were involved that I could make out.

DR MEANS If there was an embolus large enough to shut off one main branch of the pulmonary artery, would it not have been suddenly fatal?

DR MALLORY I suppose so.

DR MEANS If due to embolism, we must assume small ones and subsequent retrograde thrombosis.

think of any other congenital derangement that we need consider seriously. Another remote possibility is arteriovenous fistula in the lung, which we now and then see producing strain on the right side of the heart. It is usually evident by x-ray study and is apt to produce bruits.

I am forced back for a diagnosis to the pulmonary vascular bed itself—either primary or secondary obliterative disease of the pulmonary arterial tree. One possibility is pulmonary obstruction secondary to chronic lung disease. This man gave no history of chronic pulmonary disease. He never coughed, wheezed or raised significant sputum, and there was no evidence to suggest it by x-ray study. Of course, extensive lung fibrosis with cor pulmonale can exist without much x-ray evidence in the lung itself. Is that true, Dr Wyman?

DR WYMAN Absolutely true.

DR BLAND Can it exist to that degree, Dr King, without symptoms pointing to pulmonary disease in the way of cough, wheeze or sputum?

DR DONALD S KING Almost never.

DR BLAND This patient had no lung disease. Therefore, we are left with the pulmonary arterial bed as the likely cause of his trouble. We have studied here, and Dr Castleman is now in the process of reviewing pathologically, about 12 patients with so-called primary disease of the vascular bed itself involving a variety of processes but most often an obliterative endarteritis of the smaller vessels and of unknown etiology. We have seen it in an infant a few months of age. In most cases in which we have puzzled over the cause of cor pulmonale and have not been able to identify a congenital lesion of the heart or chronic disease of the lungs, our experience has been that it usually turns out to be pulmonary endarteritis, unexplained. I am betting heavily on that possibility here. In some of the cases we are reviewing, the changes in the pulmonary vessels are secondary to showers of small emboli. Dr Castleman and I¹ reported a case two years ago of a patient we had observed clinically for eight years with a large heart and right-sided failure. The vascular system in the lungs was different from any of the others. The obstruction was limited throughout both lungs to the tertiary vessels, and some had recanalized. Elsewhere in the vascular tree there was no obstruction. The lungs were all right. We could not explain this widespread uniformly localized obstruction except that at some time or other there had been showers of emboli, all of about the same size, that had plugged these tertiary vessels throughout the lungs. There has been an occasional patient who, secondary to disease elsewhere in the body, has developed secondary thrombi in situ in the main pulmonary stems. Drs Means and Mallory² long ago reported such a case in which there was thrombosis and obstruction of the main pulmonary trunk. A few

months ago a case was discussed here in which the X-ray Department had cleverly pointed out two large pulmonary stems, one of which pulsed vigorously and was accompanied by increased vascular roots all the way out in the lung, whereas the other pulsed for a short distance and the lung was relatively avascular beyond that point. It was suggested that there must be a local pulmonary thrombus in that main vessel, and this proved to be true at autopsy. Our patient today had serious peripheral vascular disease, both arterial and venous, and had had episodes of bleeding in the lungs. The interpretation of these episodes has bothered me somewhat since with primary arterial disease in the lungs there is usually no bleeding. Actually, the blood does not adequately get to the lungs. It is pulmonary ischemia. They may or may not be cyanotic.

In conclusion I think this patient had obliterative vascular disease of the lungs. Furthermore, I believe it must have been primarily of the small vessels rather than of the large pulmonary trunks.

DR MEANS I saw this man on several admissions, and my recollection of this case is fairly vivid. But I am a little let down because I cannot find on studying the record a statement that he was cyanotic, although I have a vivid recollection that on the last admission he was somewhat cyanotic. To make a long story short, everyone knew that he had some sort of cor pulmonale, but what kind was the question. A note made by Dr Wheeler in 1945 is worth reading: "The Cardiac Group believes that this patient has chronic cor pulmonale, probably on the basis of pulmonary arterial obliterative disease. Constrictive pericarditis seems to be well ruled out by the x-ray and electrocardiographic findings, so that exploration of the heart does not seem advisable." We did not get any further than that. On several subsequent admissions he had cor pulmonale and chronic insufficiency, and no one knew beyond that just what the situation was. I wrote last November in the record "As far as I can make out the fundamental nature of this cardiopathy remains a mystery. Cor pulmonale, yes, but due to what? I would still cling to the possibility of pulmonary-artery thrombosis. He has tight ascites, which diuretics no longer relieve completely. I see no objection to an abdominal tap as symptomatic treatment." That is all I contributed to this situation. We might later come back to the case Dr Bland mentioned.

DR BLAND I assume that this patient's heart was not catheterized? That would have excluded a shunt.

DR MALLORY It was considered and believed to be too dangerous.

DR HAROLD E. ELRICH He had Buerger's disease of the leg. Do you think there is any tie-up between pulmonary-artery disease and that?

obstruction due to adhesions of the small intestine I think it is unlikely in this particular patient, but it is something one should always think of when one sees a scar on the abdomen with an acute abdominal condition.

The physical examination was essentially negative, I think, except for the fact that she had diffuse abdominal tenderness, most marked in the right lower quadrant and epigastrium. It is of significance that the temperature was normal—98.6°F. I presume that is to be relied upon and, if so, rules out the question of peritonitis at the time that she was admitted so that I doubt that she had a condition at that time that was producing peritonitis. The cardiovascular system was in a satisfactory condition for her age. The blood pressure was 175 systolic, 80 diastolic. She had not lost much blood, since the hemoglobin was 14 gm, unless she was dehydrated, which can elevate the hemoglobin. We have no other figure on the hemoglobin so if she was bleeding, I will have to leave that to Dr. Mallory to tell us about.

The serum amylase was 45 units per 100 cc. I believe in our laboratory the normal is somewhere in the vicinity of 30 units, is that right, Dr. Mallory?

DR. TRACY B. MALLORY: Yes.

DR. LINTON: The serum amylase was slightly elevated. Undoubtedly those taking care of her were thinking of acute pancreatitis, which one should consider in a patient complaining of epigastric pain and the other associated symptoms. I would say that 45 units of serum amylase was equivocal, it does not help one way or the other in making a diagnosis of pancreatitis. If she had pancreatitis beginning four weeks before admission, one would expect a normal serum amylase after that long a period. As a matter of fact, the determination usually returns to normal fairly promptly when an acute pancreatitis develops—I think within a matter of forty-eight hours. The other point regarding serum amylase is that it is a test that cannot be relied on too much to make a diagnosis of pancreatitis because there are other acute abdominal conditions, even biliary-tract disease, that give an elevation, as I believe this patient demonstrates, although the elevation was not very marked.

The nonprotein nitrogen was normal. From the surgical point of view the x-ray films are of interest in any patient who has an acute abdominal condition in which one suspects intestinal obstruction, and I think one would suspect it in this case.

DR. STANLEY M. WYMAN: The posteroanterior film of the chest shows the lung fields grossly clear. The heart shadow is not remarkable for a woman of this age. There is no evidence of gas beneath either leaf of the diaphragm. The liver shadow and the spleen do not appear unusual. The lateral view of the chest shows an increase in the anteroposterior diameter, I believe, in keeping with the patient's given age. Plain films of the abdomen

show again that the liver is grossly normal, and the spleen not enlarged. This one loop of gas-filled bowel certainly suggests small bowel, probably jejunum, and it is wider than usual, but I think it is insufficient evidence to make a flat-footed diagnosis of intestinal obstruction. I believe the small, round shadow of calcification described may possibly lie in cartilage. The bones are osteoporotic but show no definite destruction. I cannot identify any unusual soft-tissue masses.

DR. LINTON: A plain abdominal film in a patient whom one suspects of having intestinal obstruction is an extremely important diagnostic aid because by means of it one can frequently detect early intestinal obstruction and certainly can readily detect an advanced intestinal obstruction. My opinion on looking at these x-ray films and listening to Dr. Wyman's description of them is that this patient obviously did not have intestinal obstruction of sufficient degree to explain the nausea and vomiting—as well as the fact that she had diarrhea, which would be hard to connect with intestinal obstruction. The x-ray film on the left shows even less gas than one usually sees in a plain abdominal film. Do you agree?

DR. WYMAN: That is true. On the far right there is a little gas in the colon and in the one loop that represents presumable jejunum.

DR. LINTON: I feel quite sure then that we can rule out intestinal obstruction as the cause of her symptoms. The white-cell count twelve hours after admission was 22,000, indicating some pathologic process sufficient to increase the count which, as a matter of fact, increased from 16,000 to 22,000. Of extreme significance, I think, is the fact that the blood pressure dropped to 125 systolic, 70 diastolic, and that the pulse rose to 160. Something was going on within the abdomen that had produced these changes, which apparently had been rather dramatic as they came on within twelve hours of admission. Associated with that she had the terrific bouts of pain that made her writhe about. Her condition did not improve. The peristaltic sounds in the abdomen were not particularly marked, some were hyperactive, which I cannot make much out of. Someone must have thought she had either common-duct colic or ureteral colic because calcium gluconate was given, intravenously, I presume. But as one might expect, it did her no good. She obviously was getting worse, and for that reason she was taken to the operating room for an exploratory laparotomy.

In summary, I think that she had something involving the intestinal tract. I do not believe it involved the stomach. It was not acute appendicitis with peritonitis, for I believe the condition had been going on too long. One always thinks of appendicitis, even in this elderly age group. It seems unlikely that it was a malignant lesion. At least we have insufficient evidence to make a diagnosis of

DR MALLORY That is possible. We found no evidence of infarct, however, which would help back up such an opinion.

DR MEANS Am I right in thinking that in the case we reported no such extensive process in the small arterioles prevailed? The process was largely confined to the right main pulmonary artery, which was totally occluded just as this one was. A point of interest in that case was that the bronchial artery was huge, about as large as my finger, and furnished nutrition to the lung adequately. In this patient the autopsy was done elsewhere, and the tissue was in such a state that you could not determine whether or not the bronchial artery was enlarged.

DR MALLORY In the microscopical sections we could identify apparently enlarged branches of the bronchial artery but were unable to identify the main trunk.

CASE 35082

PRESENTATION OF CASE

A seventy-three-year-old widow entered the hospital complaining of epigastric pain with vomiting.

Four weeks prior to admission she suffered an episode of dull, nonradiating, epigastric pain with nausea, vomiting, diarrhea and a temperature of 101°F. She was seen by her physician, and a diagnosis of acute gastroenteritis was made. About one week later she began to experience almost daily episodes of steady, epigastric pain, lasting for two or three hours and relieved by morphine. These attacks were associated with nausea and occasional vomiting. There was probable aggravation of the pain by the taking of food. No history of right-upper-quadrant pain, fatty-food intolerance or jaundice was elicited. There were no previous symptoms suggestive of ulcer. She had lost about 15 pounds during the month prior to admission.

Twenty years previously a pelvic operation was performed, the exact nature of which was not known.

Physical examination revealed a senile, uncooperative, slightly disoriented, elderly woman. The heart was not enlarged, the aortic second sound was greater than the pulmonic second, and a Grade I systolic murmur was present at the apex. There was diffuse abdominal tenderness, most marked in the right lower quadrant and midepigastrium, with slight muscular spasm in the epigastrium. No masses were felt, and no peristalsis was heard. She was retching during part of the examination. A lower abdominal, midline scar was present.

The temperature was 98.6°F, the pulse 120, and the respirations 22. The blood pressure was 175 systolic, 80 diastolic.

Examination of the blood showed a hemoglobin of 14 gm and a white-cell count of 15,950, with 89 per cent neutrophils. Urinalysis was negative. A serum amylase was 45 units per 100 cc, the chloride was 104 milliequiv per liter, and the nonprotein nitrogen was 18 mg per 100 cc. A chest x-ray examination appeared normal. There was no free air under the diaphragm. A plain film of the abdomen showed a moderate amount of gas scattered throughout the large bowel. One small loop of gas-filled small bowel was present in the left upper quadrant. This did not have the appearance of a small-bowel obstruction. There was one small oval calcification, 3 mm in diameter, present in the right side of the abdomen adjacent to the right border of the second lumbar vertebra. This appeared to be outside the kidney. Its exact nature could not be determined.

Following admission she complained of increased abdominal pain. The white-cell count twelve hours after admission was 22,000, the blood pressure was 125 systolic, 70 diastolic, and the pulse 160. She was observed for several hours and was noted to have intermittent episodes of severe abdominal pain, which was apparently generalized and caused her to writhe in bed and to double herself up. During these episodes some hyperactive peristaltic sounds were heard. During this period the crampy pain was unrelieved by calcium gluconate intravenously. During the period of observation she developed obvious signs of shock characterized by a falling blood pressure and a rising pulse. About sixteen hours following admission an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR ROBERT R. LINTON This elderly woman obviously entered the hospital with some sort of acute abdominal condition, which, I believe, was surgical. The history is of interest in that the symptoms began one month before she was admitted to the hospital. They were characteristic of something affecting the gastrointestinal tract, since she had nausea and vomiting and associated with that she also had severe pain, apparently sufficient to require morphine—I presume by injection.

The past history is of interest in that there are symptoms suggestive of a lesion such as a duodenal or a gastric ulcer. Her dietary habits certainly make one think that she was not suffering from colitis or enteritis. I believe biliary-tract disease can be ruled out for the same reason. Perhaps of significance, especially to a surgeon, this patient with an acute abdominal condition (relatively acute at least) had had a pelvic operation twenty years before so that one cannot help considering in the differential diagnosis the possibility of intestinal

obstruction due to adhesions of the small intestine I think it is unlikely in this particular patient, but it is something one should always think of when one sees a scar on the abdomen with an acute abdominal condition.

The physical examination was essentially negative, I think, except for the fact that she had diffuse abdominal tenderness, most marked in the right lower quadrant and epigastrium. It is of significance that the temperature was normal—98.6°F. I presume that is to be relied upon and, if so, rules out the question of peritonitis at the time that she was admitted so that I doubt that she had a condition at that time that was producing peritonitis. The cardiovascular system was in a satisfactory condition for her age. The blood pressure was 175 systolic, 80 diastolic. She had not lost much blood, since the hemoglobin was 14 gm, unless she was dehydrated, which can elevate the hemoglobin. We have no other figure on the hemoglobin so if she was bleeding, I will have to leave that to Dr. Mallory to tell us about.

The serum amylase was 45 units per 100 cc. I believe in our laboratory the normal is somewhere in the vicinity of 30 units, is that right, Dr. Mallory?

DR. TRACY B. MALLORY: Yes.

DR. LINTON: The serum amylase was slightly elevated. Undoubtedly those taking care of her were thinking of acute pancreatitis, which one should consider in a patient complaining of epigastric pain and the other associated symptoms. I would say that 45 units of serum amylase was equivocal, it does not help one way or the other in making a diagnosis of pancreatitis. If she had pancreatitis beginning four weeks before admission, one would expect a normal serum amylase after that long a period. As a matter of fact, the determination usually returns to normal fairly promptly when an acute pancreatitis develops—I think within a matter of forty-eight hours. The other point regarding serum amylase is that it is a test that cannot be relied on too much to make a diagnosis of pancreatitis because there are other acute abdominal conditions, even biliary-tract disease, that give an elevation, as I believe this patient demonstrates, although the elevation was not very marked.

The nonprotein nitrogen was normal. From the surgical point of view the x-ray films are of interest in any patient who has an acute abdominal condition in which one suspects intestinal obstruction, and I think one would suspect it in this case.

DR. STANLEY M. WYMAN: The posteroanterior film of the chest shows the lung fields grossly clear. The heart shadow is not remarkable for a woman of this age. There is no evidence of gas beneath either leaf of the diaphragm. The liver shadow and the spleen do not appear unusual. The lateral view of the chest shows an increase in the anteroposterior diameter, I believe, in keeping with the patient's given age. Plain films of the abdomen

show again that the liver is grossly normal, and the spleen not enlarged. This one loop of gas-filled bowel certainly suggests small bowel, probably jejunum, and it is wider than usual, but I think it is insufficient evidence to make a flat-footed diagnosis of intestinal obstruction. I believe the small, round shadow of calcification described may possibly lie in cartilage. The bones are osteoporotic but show no definite destruction. I cannot identify any unusual soft-tissue masses.

DR. LINTON: A plain abdominal film in a patient whom one suspects of having intestinal obstruction is an extremely important diagnostic aid because by means of it one can frequently detect early intestinal obstruction and certainly can readily detect an advanced intestinal obstruction. My opinion on looking at these x-ray films and listening to Dr. Wyman's description of them is that this patient obviously did not have intestinal obstruction of sufficient degree to explain the nausea and vomiting—as well as the fact that she had diarrhea, which would be hard to connect with intestinal obstruction. The x-ray film on the left shows even less gas than one usually sees in a plain abdominal film. Do you agree?

DR. WYMAN: That is true. On the far right there is a little gas in the colon and in the one loop that represents presumable jejunum.

DR. LINTON: I feel quite sure then that we can rule out intestinal obstruction as the cause of her symptoms. The white-cell count twelve hours after admission was 22,000, indicating some pathologic process sufficient to increase the count which, as a matter of fact, increased from 16,000 to 22,000. Of extreme significance, I think, is the fact that the blood pressure dropped to 125 systolic, 70 diastolic, and that the pulse rose to 160. Something was going on within the abdomen that had produced these changes, which apparently had been rather dramatic as they came on within twelve hours of admission. Associated with that she had the terrific bouts of pain that made her writhe about. Her condition did not improve. The peristaltic sounds in the abdomen were not particularly marked, some were hyperactive, which I cannot make much out of. Someone must have thought she had either common-duct colic or ureteral colic because calcium gluconate was given, intravenously, I presume. But as one might expect, it did her no good. She obviously was getting worse, and for that reason she was taken to the operating room for an exploratory laparotomy.

In summary, I think that she had something involving the intestinal tract. I do not believe it involved the stomach. It was not acute appendicitis with peritonitis, for I believe the condition had been going on too long. One always thinks of appendicitis, even in this elderly age group. It seems unlikely that it was a malignant lesion. At least we have insufficient evidence to make a diagnosis of

cancer of the large or small bowel. I think the most likely diagnosis in this case is thrombosis of the mesenteric vessels, either veins or arteries. And in view of the fact that this condition had been going on for several weeks, I would say that it was venous thrombosis of the mesenteric vessels, probably the superior mesenteric vein.

DR CHESTER M. JONES: Is the first film at all suggestive of free fluid in the abdominal cavity? There is a ground-glass appearance over the entire abdominal area.

DR WYMAN: One cannot judge, because the film was taken for the chest primarily. Therefore, there was insufficient penetration of the abdomen, and one would find this appearance even in normal persons.

DR JONES: If that were an ordinary abdominal film, it would be exciting.

DR WYMAN: Absolutely.

DR F. DENNETTE ADAMS: Can you, so to speak, rule out obstruction when there is no dilated bowel? In other words, if this condition is present, does it work just as well in reverse?

DR WYMAN: I think one may miss dilated loops readily on a film taken in the supine or prone position. We have been fooled in such cases because the bowel was filled with fluid, obscuring the gas shadows to a great extent. If these people are placed upright, the fluid levels are readily apparent.

DR LINTON: The gas in the right-hand film is in the colon. Therefore, she could not have had small-bowel obstruction, and she was too sick to have had large-bowel obstruction, I believe.

CLINICAL DIAGNOSIS

Perforated carcinoma of stomach

DR LINTON'S DIAGNOSIS

Acute mesenteric thrombosis, venous

ANATOMICAL DIAGNOSES

*Infarction of small intestine, cause undetermined
Arteriosclerosis, generalized, severe aortic, slight
coronary and mesenteric*

Nephrosclerosis, moderate

Polyp of cecum

PATHOLOGICAL DISCUSSION

DR MALLORY: I do not see either Dr Scannell or Dr Moorman in the audience. They operated on this patient and found on entering the abdomen diffuse discoloration of the small bowel, beginning about 16 cm below the ligament of Treitz and extending almost down to the ileum. They could not feel pulsations in the vessels of the mesentery. Going back to the aorta they were able to feel pulsations of the trunk of the superior mesenteric artery for a distance of 1.5 or 2 cm, where there was a zone that felt a little thickened where the pul-

sations disappeared. They made a diagnosis of thrombosis of the superior mesenteric artery and believed that any surgical treatment was impossible in view of the fact that the entire small bowel appeared to be involved. The patient died about twelve hours later.

At the time of autopsy the resident pathologist, having had experience with a very similar case, refused to dissect the mesenteric vessels until both surgeons taking part in the operation were present. The three of them then examined the vessels with extreme care, and no thrombus was found anywhere in the distribution of the mesenteric artery. On the other hand, the entire small bowel was completely gangrenous by that time. The veins of the mesentery were likewise entirely free from thrombi so that there appears to have been a functional occlusion of the mesenteric artery with no anatomic basis and a strong suggestion that it was spastic in origin. The question of spasm in an intra-abdominal vessel is one that has been debated a great deal. Many people are skeptical of it. Dunphy,* at the Peter Bent Brigham Hospital, was interested in it a few years ago and concluded that in many cases functional obstruction of the mesenteric artery alone could produce episodes of acute intra-abdominal pain, often preceding a final thrombosis. He argued that this might be spastic occlusion of the artery analogous to anginal attacks in the coronary arteries.

DR JONES: Were the arteries sclerosed?

DR MALLORY: They were markedly sclerosed.

DR LINTON: I still cannot believe that at the age of seventy-three a vessel can go into spasm, especially spasm sufficient to shut off a vessel.

DR MALLORY: The last time we reported such a situation the surgeons refused to believe it. That is why the resident insisted on their presence. They actually dissected the vessel under our eyes. We convinced them at any rate. Whether I can convince this audience, I do not know.

DR LINTON: It is a most extraordinary and interesting lesion. I have never heard of it.

DR JONES: Dr Linton commented that at this age there could not be spasm of the vessels. In coronary disease older people with stiff arteries get angina, not necessarily because of spasm but because of the extra demands on the artery at certain times, producing coronary insufficiency. After meals there may be a great demand on the mesenteric circulation that might be analogous.

DR LINTON: You mentioned that the superior mesenteric artery was occluded at the time of operation. It would be hard to imagine a vessel as large as my little finger being shut off by spasm, but I must admit one cannot refute the findings. Dr Mallory has reported. I still say that this is a most unusual and interesting case of vascular disease.

*Dunphy, J. E. Abdominal pain of vascular origin. *Am. J. M. Sc.* 192 109-113 1936.

ENDS AND MEANS

THE correspondence printed elsewhere in this issue of the *Journal* mainly concerns the action of the American Medical Association in assessing each member twenty-five dollars, only secondarily or by implication do the writers of the letters refer to compulsory health insurance or any other phase of Government participation in medicine. By an ironic turn of circumstances, these men, who have no quarrel with the Association's stand on state medicine, strongly object to the so-called "enforced" contribution, part of which was earmarked by their spokesmen as an aid in the struggle against changes imposed by force from outside the profession. It is sobering to realize that the condemna-

tion expressed represents division among those who are otherwise united in their opposition to dictation.

Among the liberties that doctors at present possess is freedom to criticize—whether the object is the Government or their own spokesmen. The opinion is properly expressed through an official organ of a society of physicians, not in the correspondence columns of the lay press, the public, which in the final analysis will decide the grave question now facing the medical profession, should not be given an unwarranted impression of undue friction and bickering within the ranks.

The strength that is inherent in union should not be lost sight of in differences of opinion about the best means of serving the interests of the American public. Regarding the acceptability of the assessment, returns so far received in Massachusetts indicate an overwhelming vote of confidence, particularly on the part of the active practitioners. Additional effective ways of countering the arguments in favor of state medicine must be found. Perhaps the best method is individual action to achieve a common end, each physician being "chairman of his Public Relations Committee."¹ The physicians may justifiably point out to their patients the full implications involved, Americans, for whom such words as "social" and "socialized" have become so disarmingly familiar as to have few terrors, might well be impressed by the connotations of the word "compulsory"—the dangerous term that, as the correspondence referred to indicates, can cause discord even among those who are united on fundamental issues. If doctors, acting independently but inspired by unity of conviction and determination, could demonstrate to their patients the achievements of free medicine in America (and the consequent benefits to the people at large) and the best means of maintaining and extending these benefits, public pressure could cause legislators to consult the medical profession in the drafting of plans and regulations vitally affecting medical practice.

Thus might the American doctor and his patient be spared the evils of Government-directed medicine as reported by one who has witnessed them at first hand. "Had they [the British medical profession] analyzed the defects in their system, presented a well conceived plan for improvements, and then

stood fast against ill advised changes, the British people might now be receiving better care and the physicians might be happier about their working milieu "2

ANOTHER BULWARK AGAINST SOCIALIZED MEDICINE

SOUND public-health programs providing state-wide coverage can best be administered through the establishment of efficient and economic local health departments, employing full-time, trained and experienced personnel. The American Medical Association has for many years recognized the urgent need for this type of health coverage and strongly supports sound action to extend and strengthen local health services. This support has been expressed in numerous resolutions passed by the House of Delegates and is Point 2 of the Association's Ten Point Health Program.

Through the remarkable combination of complacency, inadequate legislation and local autonomy, Massachusetts has succeeded in ignoring its local health programs, which for the most part compare unfavorably with those established in other states. An article in a recent issue of the *Journal** outlined the severe deficiencies in this field that exist throughout the Commonwealth. Where does the fault lie?

Appreciation of the need for the promotion and support of adequate local health services in Massachusetts is with few exceptions limited to practicing physicians who have knowledge and interest in their local community's health programs. Unfortunately, their numbers are few.

The solution of this critical problem lies in community interests and action. It devolves upon the physician as a member of his community to exert efforts to help obtain adequate local health services. It befits him as a member of a society actively opposed to a threatened program of socialized medicine to support accepted and necessary measures that will ensure the free practice of medicine.

*Archibald, R. Fiore, A. and Skvirsky, S. L. Local health services in Massachusetts. *New Eng J Med* 239:858-861, 1948

The people purchase health service. Whether that purchase is accomplished directly between patient and physician or indirectly, through the tax dollar, it remains that health, as a commodity, constitutes big business, and the consumer's voice has grown louder in its demand for more service.

The physician has his choice. He may retain his complacency, ignore the demand and express open resentment of the threatened program of socialized medicine, or he may make constructive efforts to satisfy these demands by the promotion, at the local level, of adequate, basic health services through measures endorsed by the American Medical Association.

Such a program of full-time local health departments providing efficiently and economically administered health services is the physician's disturbingly obvious but as yet unrecognized weapon against the threatened advances on his right to practice independent of governmental control.

The following statement is quoted in full, as it appeared in the recent January 19 issue of the *Bulletin of the Middlesex East District Medical Society*.

Excerpts from Mr. Ewing's speech before the State and Territorial health officers in Washington: "Success of the government health plan depends on the people themselves and what they are willing to do about it." He then stated in brief that each community must be organized, and state and local campaigns of education must be planned, and that he is putting this up to the health officers to undertake this job in their states. There it is gentlemen, and what are we, as a Medical Society, going to do about it?

It should be pointed out that *any* health program "depends on the people themselves and what they are willing to do about it" and that physicians constitute a not unimportant segment of these people. Let them look to the stark inadequacies that exist in their own local health services for their answer to the question "What are we as a Medical Society going to do about it?"

While the Federal Security Administrator has thrown the challenge to state health officers to put across his program, there is no evidence that the health officers have accepted the challenge. As a matter of fact, health officers are the practitioner's strongest ally in his struggle against political inter-

ference. The failure on the part of many physicians to comprehend the basic underlying principles of public-health services has contributed enormously to the growth of the ever-lengthening shadow of governmental control of medicine.

Unwarranted criticism based on superficial knowledge assumes an importance second only to that of complacency in its power to destroy any unified group attack against the threat of political control.

Promotion of basic health services at the local level is sorely needed. With few exceptions, Massachusetts lags far behind other states in their efforts to satisfy these needs.

There are now before the Massachusetts General Court two bills that, if passed, will facilitate the promotion and maintenance of local health units throughout the Commonwealth. At the federal level, the eighty-first Congress has under consideration proposed legislation to further this program. Senator Virgil Chapman, who together with Senator Leverett Saltonstall and others has introduced the Local Public Health Units Act of 1949 (S. 522), has commented that the "creation of such a system would constitute the surest bulwark against socialized medicine which many of us think is undesirable in America."

The physicians of Massachusetts have it within their power to strengthen that bulwark, through their support and interest in the program to provide all the people of the Commonwealth with basic local health facilities.

NATION-WIDE AND WORLD-WIDE PROGRAM FOR CONTROL OF INFLUENZA

ONE of the most important limitations of the protective value of vaccination against influenza is the occurrence of variations among strains of influenza virus. This fact became particularly prominent during the epidemic that occurred in the winter and spring of 1947. That epidemic was caused by a strain of influenza A that was antigenically distinct from the influenza A strains that had been incorporated in the polyvalent influenza vaccines in use prior to that time. The evidence came from

the demonstration that experimental animals immunized with the standard strains that were contained in commercial vaccines failed to protect against infection with the strain that was the cause of the 1947 influenza epidemic. What is more, the incidence of influenza among persons who had been vaccinated with the commercial vaccines shortly before this epidemic was the same as that among persons who had not been vaccinated. By contrast, during the epidemic of 1945-1946, which was due to influenza B, the protection conferred by the Lee strain that was incorporated in the standard vaccines seems to have been of high grade, as evidenced by the low incidence of influenza among vaccinated persons as compared with the unvaccinated controls during that epidemic.

Another limitation in the use of influenza vaccines is the relatively short duration of the protection that results from vaccination with influenza viruses. This necessitates the administration of the vaccines within a few weeks of an anticipated influenza epidemic, and since the exact time of occurrence of such epidemics cannot be predicted with certainty, it becomes necessary to repeat vaccinations in the fall of each year before the season for respiratory infections begins. One of the outstanding features of an influenza epidemic, when it occurs in any given area, is its explosive character. Adequate protection following vaccination, however, does not usually occur in less than one or two weeks. One cannot, therefore, expect to isolate an epidemic strain from any given area, prepare a vaccine from that strain that will pass potency and sterility tests and have the vaccine distributed and administered to the exposed population in the same area in time to do any good.

Fortunately, some pandemics in the past have been preceded by small and relatively localized outbreaks before the major epidemics reached their peak in the great centers of population. If these small outbreaks can be recognized early, the strains isolated and identified and their antigenic relation to known strains that are in use in the available vaccines determined promptly, it may be possible to choose from those available or to prepare more satisfactory vaccines for use in the major epidemic. This, in turn, may considerably increase the chance

for the vaccine to have a protective effect when the epidemic strikes

In this country the surgeons general of the Army, Navy, Air Forces and Public Health Service have developed a plan based upon this principle by which it is hoped to prevent a recurrence of a serious epidemic like that of 1918. This plan is part of an international program that was set up by the World Health Organization last year to study influenza and to aid physicians and health officers in the control of the disease. An influenza information center to serve as headquarters in the United States has been established at the National Institutes of Health in Bethesda, Maryland. The specific objectives of the world-wide program are to identify new strains of influenza virus as they appear, and to evaluate their usefulness for incorporation into influenza vaccines.

It is anticipated that as soon as a significant outbreak of a respiratory disease suspected of being influenza is reported in a given community, the Influenza Information Center will alert diagnostic laboratories in the region asking them to carry out serologic tests on patients for the presence of antibody against the influenza virus. Certain laboratories will also be asked to assign to the affected community a team of investigators experienced in the technics of isolating the virus. As soon as these investigators have isolated a new strain of virus they will send it at once for complete antigenic analysis to an established strain-study center of the Influenza Information Center, and appropriate strains of virus that have been isolated will be considered for possible inclusion in commercial vaccines.

The international influenza program was proposed during the Fourth International Congress for Microbiology in Copenhagen in July, 1947. Two months after that meeting, an international influenza center was established at the National Institute for Medical Research in London. The World Health Organization at its first World Health Assembly approved continuance of that center and recommended that all nations be invited to set up organizations to collaborate with it. In this country the appropriate authorities decided to establish the Influenza Information Center at Bethesda, Maryland, which would administer the program in this country and would serve as a liaison office

between the International Influenza Center and participating American laboratories.

Obviously the key to the success of this program is the co-operation of physicians in the early recognition and reporting of cases suspected of being influenza.

RED CROSS CAMPAIGN

THE annual campaign of the American Red Cross which will be conducted in March, once again draws attention to the needs, as well as the achievements of that organization. Community co-operation is essential in all work done by the Red Cross, whether it is educational or preventive (instruction in first aid, water safety, accident prevention, home nursing and nutrition) or remedial (aid to veterans, servicemen and civilians, both hospitalized and ambulatory). An illustration of the value of public partnership is provided by the fact that 64,000 persons have offered to donate blood, and that blood has been distributed to more than 350 hospitals. The Red Cross asks that the generous response in previous years be continued—that the people contribute the money, time and moral support necessary to make the 1949 campaign a success and to guarantee continued services in the future.

No one needs to be reminded of the achievements of the Red Cross where the need is greatest, the help is forthcoming. Last year more than three hundred disasters occurred in widely separated communities, and organized and efficient efforts were available in the work of the community volunteers and full-time staff of the Red Cross. Everyone is urged to contribute generously to this year's campaign; community need is met by community partnership, and when disaster strikes again, the help of the Red Cross will be vital.

MASSACHUSETTS MEDICAL SOCIETY

HOTEL ACCOMMODATIONS FOR THE ANNUAL MEETING

Headquarters for the one hundred and sixty-eighth annual meeting of the Society, to be held on May 24, 25 and 26, will be at the Hotel Sheraton, 50 Franklin Street, Worcester, Massachusetts. As accommodations in the hotel are limited, it is suggested that fellows wishing to attend the meeting reserve their rooms as soon as possible.

COMMITTEE ON ARRANGEMENTS

DEATHS

CARD — Walton G Card, M D, of Haverhill, died on November 11. He was in his sixtieth year.

Dr Card received his degree from Tufts College Medical School in 1925. He was a member of the staff of Hale Hospital and a fellow of the American Medical Association.

His mother, two brothers and one sister survive.

GILLON — Charles J C Gillon, M D, of Taunton, died on January 15. He was in his sixtieth year.

Dr Gillon received his degree from Harvard Medical School in 1915. He was chief of the Eye, Ear, Nose and Throat Service of Morton Hospital and consultant at Taunton State Hospital.

His widow, a son and a daughter survive.

MACKEY — William M MacKay, M D, of Waltham, died on January 31. He was in his sixtieth year.

Dr MacKay received his degree from Queen's University Faculty of Medicine, Kingston, Ontario, in 1914. He was senior physician of Middlesex County Sanatorium and a fellow of the American Medical Association.

His widow, three brothers and two sisters survive.

WELLER — John H Weller, M D, of Bridgewater, died on November 19. He was in his seventieth year.

Dr Weller received his degree from College of Physicians and Surgeons of Baltimore in 1909. He was senior physician at the Bridgewater State Farm and was a member of the New England Society of Psychiatry and a fellow of the American Medical Association.

His widow and a daughter survive.

POSTGRADUATE LECTURE COURSE

The fourth Postgraduate Lecture Course, which has been arranged by the Committee on Postgraduate Medical Education, Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health, will begin on March 7. The meetings will be held at Sanders Theater in Memorial Hall, Harvard University, Cambridge. These lectures are designed for all physicians of Massachusetts and surrounding states, medical officers, hospital residents, interns, medical students and postgraduate students.

All those who plan to attend but have not enrolled should do so immediately by either returning the post card recently forwarded to all physicians in Massachusetts or addressing a post card or letter directly to Postgraduate Lecture Course Committee, Massachusetts Medical Society, 8 Fenway, Boston 15.

The detailed program for the course is as follows:

Monday, March 7 PUBLIC HEALTH Chairmen James S Simmons and John F Conlin

7 00-7 30 Local Health Departments Hugh R. Leavell, professor of public-health practice, Harvard School of Public Health

7 30-8 00 Maternal and Child Health Samuel B Kirkwood, assistant professor of maternal health and instructor in obstetrics and gynecology, Harvard School of Public Health

8 00-8 30 School Health Stuart S Stevenson, assistant professor of child health, Harvard School of Public Health.

8 30-9 00 Industrial Health Albert O Seeler, assistant professor of industrial medicine, Harvard School of Public Health.

Wednesday, March 9 CARDIOVASCULAR DISEASE Chairmen Laurence B Ellis and Eugene Eppinger

4 00-4 30 The National Heart Institute Paul D White, chief consultant, National Heart Institute, executive director, National Advisory Heart Council, and formerly clinical professor of medicine, Harvard Medical School, and physician, Massachusetts General Hospital

4 30-5 15 Preventive Measures in the Management of Heart Disease David Ruststein, professor of preventive medicine, Harvard Medical School.

5 15-5 30 The Role of the New England Heart Association in Sponsoring Local Heart Programs Laurence B Ellis, president, New England Heart Association, assistant clinical professor of medicine, Harvard Medical School, associate physician, Thorndike Memorial Laboratory, and assistant visiting physician, Boston City Hospital

5 30-6 00 The Diagnosis and Treatment of Angina Pectoris Joseph E F Riseman, associate in medicine, Harvard Medical School, and visiting physician, Beth Israel Hospital.

Monday, March 14 CARDIOVASCULAR DISEASE Chairmen Laurence B Ellis and Eugene Eppinger

7 00-7 45 Curable Heart Disease C Sidney Burwell, research professor of clinical medicine, Harvard Medical School, and physician, Peter Bent Brigham Hospital.

7 45-8 15 The Use and Abuse of Laboratory Aids (Including Electrocardiography) in the Evaluation of Patients with Heart Disease Richard A Bloomfield, instructor, Harvard Medical School, assistant physician, Thorndike Memorial Laboratory, and junior visiting physician, Boston City Hospital

8 15-9 00 The Diagnosis and Treatment of Rheumatic Fever — Its Complications Benedict F Massell, clinical associate in pediatrics, Harvard Medical School, associate research director, House of the Good Samaritan, and chief, Rheumatic Fever Division, Children's Hospital

Wednesday, March 16 INDUSTRIAL HEALTH AND ACCIDENTS Chairmen Henry C Marble and Daniel L Lynch

4 00-4 20 Industrial Health — Its Contributions and Opportunities Carl M Peterson, secretary, Council on Industrial Health, American Medical Association

4 20-4 40 Injuries to the Hand Edward Hamlin, assistant surgeon, Massachusetts General Hospital

4 40-5 00 Industrial Diseases Albert O Seeler, professor of industrial diseases, Harvard School of Public Health

5 00-5 20 Examination of Back Injuries Carroll Larson, assistant surgeon, Department of Orthopedics, Massachusetts General Hospital

5 20-5 40 Common Causes of Contact Dermatitis George E Morris, consultant in Industrial Dermatology, Boston

5 40-6 00 Records and Reports in Industrial Accidents Henry C Marble, consulting surgeon, Massachusetts General and Faulkner hospitals

Monday, March 21 INFECTIOUS DISEASES Chairmen Chester S Keefer and Louis Weinstein

7 00-7 25 Newer Antibiotic Agents — Polymyxin, Aureomycin and Chloromycetin Maxwell Finland, physician-in-chief, Fourth Medical Service, Boston City Hospital, and assistant professor of medicine, Harvard Medical School.

for the vaccine to have a protective effect when the epidemic strikes

In this country the surgeons general of the Army, Navy, Air Forces and Public Health Service have developed a plan based upon this principle by which it is hoped to prevent a recurrence of a serious epidemic like that of 1918. This plan is part of an international program that was set up by the World Health Organization last year to study influenza and to aid physicians and health officers in the control of the disease. An influenza information center to serve as headquarters in the United States has been established at the National Institutes of Health in Bethesda, Maryland. The specific objectives of the world-wide program are to identify new strains of influenza virus as they appear, and to evaluate their usefulness for incorporation into influenza vaccines.

It is anticipated that as soon as a significant outbreak of a respiratory disease suspected of being influenza is reported in a given community, the Influenza Information Center will alert diagnostic laboratories in the region asking them to carry out serologic tests on patients for the presence of antibody against the influenza virus. Certain laboratories will also be asked to assign to the affected community a team of investigators experienced in the technics of isolating the virus. As soon as these investigators have isolated a new strain of virus they will send it at once for complete antigenic analysis to an established strain-study center of the Influenza Information Center, and appropriate strains of virus that have been isolated will be considered for possible inclusion in commercial vaccines.

The international influenza program was proposed during the Fourth International Congress for Microbiology in Copenhagen in July, 1947. Two months after that meeting, an international influenza center was established at the National Institute for Medical Research in London. The World Health Organization at its first World Health Assembly approved continuance of that center and recommended that all nations be invited to set up organizations to collaborate with it. In this country the appropriate authorities decided to establish the Influenza Information Center at Bethesda, Maryland, which would administer the program in this country and would serve as a liaison office

between the International Influenza Center and participating American laboratories.

Obviously the key to the success of this program is the co-operation of physicians in the early recognition and reporting of cases suspected of being influenza.

RED CROSS CAMPAIGN

THE annual campaign of the American Red Cross, which will be conducted in March, once again draws attention to the needs, as well as the achievements, of that organization. Community co-operation is essential in all work done by the Red Cross, whether it is educational or preventive (instruction in first aid, water safety, accident prevention, home nursing and nutrition) or remedial (aid to veterans, servicemen and civilians, both hospitalized and able bodied). An illustration of the value of public partnership is provided by the fact that 64,000 persons have offered to donate blood, and that blood has been distributed to more than 350 hospitals. The Red Cross asks that the generous response in previous years be continued—that the people contribute the money, time and moral support necessary to make the 1949 campaign a success and to guarantee continued services in the future.

No one needs to be reminded of the achievements of the Red Cross where the need is greatest, the help is forthcoming. Everyone is urged to contribute generously to this year's campaign; community need is met by community partnership, and when disaster strikes again, the help of the Red Cross will be vital.

MASSACHUSETTS MEDICAL SOCIETY HOTEL ACCOMMODATIONS FOR THE ANNUAL MEETING

Headquarters for the one hundred and sixty-eighth annual meeting of the Society, to be held on May 24, 25 and 26, will be at the Hotel Sheraton, 50 Franklin Street, Worcester, Massachusetts. As accommodations in the hotel are limited, it is suggested that fellows wishing to attend the meeting reserve their rooms as soon as possible.

COMMITTEE ON ARRANGEMENTS

4 25-4 45 **Neoplasm of the Spine and Cord** James L. Poppen, neurosurgeon, Lahey Clinic and New England Deaconess and New England Baptist hospitals

4 50-5 10 **Injuries of the Spine and Cord** Donald Munro, associate professor of neurosurgery, Harvard Medical School and Boston University School of Medicine, and chief, Department of Neurosurgery, Boston City Hospital

5 15-5 35 **Infectious Lesions of the Spine and Cord** James C. White, associate professor of surgery, Harvard Medical School, and chief, Neurosurgical Service, Massachusetts General Hospital

5 40-6 00 **Ruptured Intervertebral Disk** W. Jason Mixer, member, Board of Consultation, Massachusetts General Hospital, and consultant on staffs of Beth Israel, Mt. Auburn and New England Deaconess hospitals

Monday, April 18 PEDIATRICS Chairmen Warren R. Sisson and Charles A. Janeway

4 00-5 00 **Allergy in Childhood** Lewis Webb Hill, visiting physician and chief of Allergy Clinic, Children's Hospital, and clinical associate in pediatrics, Harvard Medical School

5 00-6 00 **Question Period**

Wednesday, April 20 PSYCHIATRY Chairman Harry C. Solomon

4 00-5 00 **Office Practice in Psychiatry** Donald J. MacPherson, instructor in medicine, Harvard Medical School, and associate in medicine, Peter Bent Brigham Hospital.

5 00-6 00 **The Psychoses and the Mental Hospital** Walter E. Barton, superintendent, Boston State Hospital

Monday, April 25 CLINICAL PROBLEMS IN INTERNAL MEDICINE (The Recognition of Some Rare but Often Curable Diseases Which Masquerade as Common Disorders) Chairmen Samuel H. Proger and Lewis Dexter

7 00-7 25 **Neurology** Raymond D. Adams, assistant professor of neurology, Harvard Medical School, lecturer in neurology, Tufts College Medical School, and visiting neurologist and neuropathologist, Boston City Hospital

7 30-7 55 **Hematology** William Dameshek, professor of clinical medicine, Tufts College Medical School, and consultant in hematology and visiting physician Joseph H. Pratt Diagnostic Hospital

8 00-8 25 **Cardiology** Samuel A. Levine, assistant professor of medicine, Harvard Medical School, and physician, Peter Bent Brigham Hospital

8 30-8 55 **Endocrinology** Elmer C. Bartels, physician, Department of Internal Medicine, Lahey Clinic and physician, New England Baptist and New England Deaconess hospitals. Frank N. Allan, executive director, Department of Internal Medicine, Lahey Clinic, and physician, New England Baptist and New England Deaconess hospitals, and Lewis M. Hurxthal, head of Department of Internal Medicine, Lahey Clinic, and physician, New England Baptist and New England Deaconess hospitals

Wednesday, April 27 FRACTURES Chairman Otto J. Hermann

4 00-4 25 **Elbow Fractures and Epiphyseal Injuries of Childhood** David S. Grice, associate orthopedic surgeon, Children's Hospital

4 25-4 50 **Injuries to Foot and Ankle** Joseph Shortell, surgeon-in-chief, Orthopedic Service, Boston City Hospital

4 50-5 00 **Question Period**

5 00-5 25 **Postoperative Care of Fractures of the Hip** Edwin F. Cave, chief, Fracture Service, Massachusetts General Hospital

5 25-5 50 **The Needs and Benefit of Medical Rehabilitation** Augustus Thorndike, chief surgeon, Department of Hygiene, Harvard University

5 50-6 00 **Question Period**

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS

The March schedule for Consultation Clinics for Crippled Children in Massachusetts under the provisions of the Social Security Act follows:

CLINIC	DATE	CLINIC CONSULTANT
Haverhill	March 2	William T. Green
Lowell	March 4	Albert H. Brewster
Salem	March 7	Paul W. Hugenberg
Gardner	March 8	Carter R. Rowe
Brockton	March 10	George W. Van Gorder
Greenfield	March 14	Charles L. Sturdevant
Springfield	March 15	Garry deN. Hough, Jr.
Pittsfield	March 16	Frank A. Slowick
Worcester	March 18	John W. O'Meara
Hyannis	March 24	Paul L. Norton
Fall River	March 28	David S. Grice

Physicians referring new patients to clinics should get in touch with the district health officer to make appointments. Patients are seen by appointment only.

MISCELLANY

AMERICAN CANCER SOCIETY

Dr. Clarence L. Scamman, director of the Division of Public Health of the Commonwealth Fund of New York from 1931 to July 15, 1948, has returned to Boston as medical director of the Massachusetts Division of the American Cancer Society.

Prior to 1931 Dr. Scamman was deputy commissioner of public health of the Commonwealth of Massachusetts.

BUSINESS MANAGER OF HARVARD UNIVERSITY MEDICAL AREA

Mr. Charles W. Greenough, formerly Budget Commissioner of the Commonwealth of Massachusetts, has been appointed business manager for the Medical Area of Harvard University. He will assist the deans with budget and business affairs of the Medical School, the School of Dental Medicine and the School of Public Health.

YOUR LEGISLATORS

want to know your opinion on matters vital to you

The Committee on Legislation of the Massachusetts Medical Society is preparing a booklet listing state legislators according to district societies. If you wish a copy, please apply to Society Headquarters, 8 Fenway, Boston 15

Name

Address

Number of copies

7 30-7 55 Antibiotic Treatment of Pneumonia William Hewitt, instructor in medicine, Boston University School of Medicine, fellow, National Institute of Health, and staff member, Evans Memorial, Massachusetts Memorial Hospitals

8 00-8 25 The Treatment of Nephrosis by Induced Measles Charles A Janeway, Thomas Morgan Rotch Professor of Pediatrics, Harvard Medical School, and physician-in-chief, Children's Hospital

8 30-8 55 Use of Chemotherapeutic Agents as Prophylaxis Benedict F Massell, clinical associate in pediatrics, Harvard Medical School, associate research director, House of the Good Samaritan, and chief of the rheumatic fever division, Children's Hospital

Wednesday, March 23 MEDICOLEGAL PROBLEMS Chairmen Alan R Moritz and Richard Ford

4 00-5 00 The Doctor as Defendant and as Witness Richard Ford, associate medical examiner of Suffolk County, and member of teaching staff, Department of Legal Medicine, Harvard Medical School

5 00-6 00 Scientific Evidence in Criminal Investigation Russell Fisher, Rockefeller Fellow, Department of Legal Medicine, Harvard Medical School

Monday, March 28 HEADACHE Chairmen James L Poppen and John B Dynes

7 00-7 45 Headache Caused by Intracranial Neoplasms James L Poppen, neurosurgeon, Lahey Clinic and New England Deaconess and New England Baptist hospitals

7 45-8 25 Migraine and Histamine Headache John B Dynes, neuropsychiatrist, Lahey Clinic, and neurologist, New England Deaconess and New England Baptist hospitals

8 25-9 00 Headaches from a Psychiatric Standpoint Robert E Arnot, research fellow in psychiatry, Harvard Medical School and Boston Psychopathic Hospital

Wednesday, March 30 GYNECOLOGY Chairman Fred Simmons

4 00-4 20 Elementary Facts Concerning the Vaginal Smear Howard M Ulfelder, assistant surgeon, Massachusetts General Hospital, and clinical associate in surgery, Harvard Medical School

4 30-4 50 Conservative Ovarian Surgery Samuel R Meaker, professor of gynecology, Boston University Medical School

5 00-5 20 Conservative Management of Endometriosis John Fallon, director, Fallon Clinic, Worcester, Massachusetts

5 30-6 00 The Physiology of Menstruation (Animated Cartoon) John Rock, clinical professor of gynecology, Harvard Medical School, and Somers H Sturgis, assistant surgeon, Massachusetts General Hospital

Monday, April 4 OBSTETRICS Chairmen M Fletcher Eades and H Bristol Nelson

7 00-7 15 X-Ray Pelvimetry and Its Clinical Interpretation Robert H Barker, Boston Lying-in Hospital

7 15-7 30 Significance of Test of Labor Luke Gillespie, assistant in obstetrics and gynecology, Harvard Medical School, and assistant obstetrician, Boston Lying-in Hospital

7 30-7 45 Antibiotics in the Treatment of Uterine Sepsis Maxwell Finland, physician-in-chief, Fourth Medical Service, Boston City Hospital, and assistant professor of medicine, Harvard Medical School

7 45-8 00 Question Period

8 00-8 20 Nonmenstrual Bleeding Diagnosis and treatment John Rock, clinical professor of gynecology, Harvard Medical School

8 20-8 40 Treatment of Toxemia of Pregnancy Duncan Reid, Richardson Professor of Obstetrics, Harvard Medical School

8 40-9 00 Question Period

Wednesday, April 6 Gastroenterology Chairmen Francis D Moore and Chester M Jones

4 00-4 20 The Treatment of Bleeding Gastric and Duodenal Ulcer John E Dunphy, senior associate in surgery, Peter Bent Brigham Hospital, and assistant professor of surgery, Harvard Medical School

4 20-4 30 Discussion

4 30-4 50 The Value of Exfoliative Cytology in the Diagnosis of Gastric Carcinoma Howard M Ulfelder, assistant surgeon, Massachusetts General Hospital, and clinical associate in surgery, Harvard Medical School

4 50-5 00 Discussion

5 00-5 20 Nutritional Problems Arising from Anastomotic Surgery Chester M Jones, physician, Massachusetts General Hospital, and clinical professor of medicine, Harvard Medical School

5 20-5 30 Discussion

5 30-5 50 Body-Fluid Replacement in Gastrointestinal Surgery Francis D Moore, surgeon-in-chief, Peter Bent Brigham Hospital, and Moseley Professor of Surgery, Harvard Medical School

5 50-6 00 Discussion

Monday, April 11 HEMATOLOGY Chairmen Joseph F Ross and Clement A Finch

7 00-7 20 The Therapeutic Use of Folic Acid and Vitamin B₁₂ William B Castle, professor of medicine, Harvard Medical School, and director, Thorndike Memorial Laboratory and Second and Fourth Medical Services (Harvard), Boston City Hospital

7 20-7 40 Hemolytic Disorders Practical applications of the Coombs test and other serologic techniques. Charles P Emerson, Jr, assistant professor of medicine, Boston University School of Medicine, and visiting physician, Massachusetts Memorial Hospitals

7 40-8 00 The Clinical Use of Blood Fractions Charles A Janeway, Thomas Morgan Rotch Professor of Pediatrics, Harvard Medical School, and physician in chief, Children's Hospital

8 00-8 20 Dicumarol and Heparin—Their Use and Abuse Clement A Finch, associate in medicine, Harvard Medical School, and associate in medicine, Peter Bent Brigham Hospital

8 20-8 40 What Can be Accomplished in Treating Leukemia and Malignant Lymphoma Joseph F Ross, associate professor of medicine, Boston University School of Medicine, and physician, Massachusetts Memorial Hospitals

8 40-9 00 Practical Management of the Rh Problem Louis K Diamond, assistant professor of pediatrics, Harvard Medical School, physician and chief of Hematology Division and director of the Blood Bank, Children's Hospital

Wednesday, April 13 DISEASES OF THE SPINAL CORD Chairmen W Jason Mixter and James C White

4 00-4 20 Congenital Anomalies of the Spine and Spinal Cord Franc D Ingraham, associate professor of surgery, Harvard Medical School, neurosurgeon-in-chief, Children's Hospital, and neurologic surgeon, Peter Bent Brigham Hospital

4 25-4 45 Neoplasm of the Spine and Cord James L Poppen, neurosurgeon, Lahey Clinic and New England Deaconess and New England Baptist hospitals

4 50-5 10 Injuries of the Spine and Cord Donald Munro, associate professor of neurosurgery, Harvard Medical School and Boston University School of Medicine, and chief, Department of Neurosurgery, Boston City Hospital

5 15-5 35 Infectious Lesions of the Spine and Cord James C White, associate professor of surgery, Harvard Medical School, and chief, Neurosurgical Service, Massachusetts General Hospital

5 40-6 00 Ruptured Intervertebral Disk W Jason Mixer, member, Board of Consultation, Massachusetts General Hospital, and consultant on staffs of Beth Israel, Mt. Auburn and New England Deaconess hospitals

Monday, April 18 PEDIATRICS Chairmen Warren R. Sisson and Charles A Janeway

4 00-5 00 Allergy in Childhood Lewis Webb Hill, visiting physician and chief of Allergy Clinic, Children's Hospital, and clinical associate in pediatrics, Harvard Medical School

5 00-6 00 Question Period

Wednesday, April 20 PSYCHIATRY Chairman Harry C Solomon

4 00-5 00 Office Practice in Psychiatry Donald J MacPherson, instructor in medicine, Harvard Medical School, and associate in medicine, Peter Bent Brigham Hospital

5 00-6 00 The Psychoses and the Mental Hospital Walter E. Barton, superintendent, Boston State Hospital

Monday, April 25 CLINICAL PROBLEMS IN INTERNAL MEDICINE (The Recognition of Some Rare but Often Curable Diseases Which Masquerade as Common Disorders) Chairmen Samuel H Proger and Lewis Dexter

7 00-7 25 Neurology Raymond D Adams, assistant professor of neurology, Harvard Medical School, lecturer in neurology, Tufts College Medical School, and visiting neurologist and neuropathologist, Boston City Hospital.

7 30-7 55 Hematology William Dameshek, professor of clinical medicine, Tufts College Medical School and consultant in hematology and visiting physician Joseph H Pratt Diagnostic Hospital

8 00-8 25 Cardiology Samuel A Levine, assistant professor of medicine, Harvard Medical School, and physician, Peter Bent Brigham Hospital

8 30-8 55 Endocrinology Elmer C Bartels, physician, Department of Internal Medicine Lahey Clinic, and physician, New England Baptist and New England Deaconess hospitals, Frank N Allan executive director, Department of Internal Medicine Lahey Clinic, and physician, New England Baptist and New England Deaconess hospitals, and Lewis M Hurxthal head of Department of Internal Medicine, Lahey Clinic, and physician, New England Baptist and New England Deaconess hospitals

Wednesday, April 27 FRACTURES Chairman Otto J Hermann

4 00-4 25 Elbow Fractures and Epiphyseal Injuries of Childhood David S Grice, associate orthopedic surgeon, Children's Hospital

4 25-4 50 Injuries to Foot and Ankle Joseph Shortell, surgeon-in-chief, Orthopedic Service, Boston City Hospital

4 50-5 00 Question Period

5 00-5 25 Postoperative Care of Fractures of the Hip Edwin F Cave, chief, Fracture Service, Massachusetts General Hospital.

5 25-5 50 The Needs and Benefit of Medical Rehabilitation Augustus Thorndike, chief surgeon, Department of Hygiene, Harvard University

CORRESPONDENCE

ASSURANCE NEEDED

To the Editor Enclosed is a copy of a letter sent to the Secretary of the American Medical Association and signed by fifteen Springfield physicians, which is forwarded for publication in your columns in case you consider it of sufficient interest

Howard N Simpson, MD
Springfield, Massachusetts

George F Lull, MD
Secretary and General Manager
American Medical Association
535 North Dearborn St
Chicago 10, Ill

Dear Dr Lull

The undersigned physicians, members of the American Medical Association, have received your letter and the enclosed literature regarding the \$25 00 assessment voted by the House of Delegates, which you choose to describe as "the democratically chosen body that speaks for the American Medical Association" The dictionary definition of "democratic" is "chosen by the people" which the House of Delegates is not and can not be according to the Association's by-laws We have no desire, at the present time, to make an issue of this, but merely wish to point out that these delegates, whom we did not elect, have seen fit to demand our support and our money, but have evinced no interest whatsoever in our opinions as to whether the assessment was justifiable or how it was to be spent Because we believe that quarreling and disunity among ourselves at this time would be disastrous we shall pay the assessment provided we may have assurances, either privately or through the press, that our money will be used in a more enlightened manner than your letter implies

Let us make it clear at this point that the undersigned are physicians deriving all, or nearly all, their income from private practice We believe in private practice, we believe in the high standards of American medicine, and we view with profound concern the impending threat to these standards inherent in any universal method of government financing and control of medicine

We also believe that the fundamental issues are becoming beclouded in the barrages and counter-barrages detonated by Mr Ewing on one side and Dr Fishbein on the other We believe no useful purpose is served by hurling insults and ridicule either at public officials or at private doctors

We believe that the American Medical Association, with its all-too-recent embrace of the Blue Cross and Blue Shield plans, is at a very definite disadvantage in the public mind

We believe that there is at the present time in this country a very definite political trend to the left Whether we like it or not we must face the facts and deal with them We hold it to be highly questionable whether a group such as the presently constituted House of Delegates is capable of successfully challenging such a political trend

We believe that the course of action outlined in your letter will lead only to defeat The public is tired of sneers, of clichés, and of propaganda A large segment of the public — the voting public — believes that the cost of medical care is too high They realize that the medical profession in America has made great advances in science, but has contributed almost nothing to the solution of the economic problems of the ill

We believe that organized medicine needs leadership and an enlightened attitude toward modern problems, that our duty to our patients and to ourselves is not to fight blindly against the administration and the trend of history, but rather to formulate a specific legislative program which is positive, forward-looking, practical, and humanitarian There are portions of the Ewing program, such as extension of public health services and improved distribution of trained manpower, which the vast majority of the profession would be willing to accept, there are changes in the present medical economic set-up which the public demands We believe that by substituting harmony

for hatred, and co-operation for conflict many of the problems may be resolved

Finally, we believe that we are better trained equipped to consult than to fight We believe that 81st Congress would be more favorably influenced by subtler suasions of the bedside manner than by the pourings of a California propaganda mill

Changes will be made, and in these changes it is better that we lead than that we be driven There is another way that American medicine can maintain its place in the world, or that we, as individuals can practice profession with dignity and with honor

Very sincerely yours,

HOWARD N SIMPSON, MD

THE TREATMENT OF HYPERTENSIVE CEREBROVASCULAR DISEASE BY SPLANCHNICECTOMY*

MAX M. PEET, M.D.,† AND EMIL M. ISBERG, M.D.‡

ANN ARBOR, MICHIGAN, AND MIAMI BEACH, FLORIDA

THE occurrence of a cerebrovascular accident is an ominous incident in the life history of a patient with arterial hypertension. It is the cause of death in almost a third of all hypertensive persons. As for those who survive such an accident, clinical experience has led to the belief that recurrences are likely and that mortality increases with each subsequent stroke.

Many hypertensive patients who had already sustained definite cerebral accidents have presented themselves at the University of Michigan Hospital, asking some preventive to ward off a recurrence. Many of these patients with hypertensive cerebrovascular disease have been treated with the surgical procedure of bilateral supradiaphragmatic splanchnicectomy and lower dorsal sympathetic ganglionectomy, in the attempt to alter beneficially the course of the disease. These patients have now been followed for a number of years, and their course subsequent to operation is the basis for this report.

To determine whether a sympathectomy has modified the natural history of hypertensive cerebrovascular disease, the course of patients not operated on must first be known. The literature on the duration of life after cerebrovascular accidents is almost entirely based on autopsy records, such reports are concerned only with patients who die after apoplexy. Thus, these records are not entirely valid for determining prognosis and mortality. Also, the several reports in the literature on survival in hypertension in general do not distinguish the patients with cerebrovascular disease.¹⁻⁶

Because the literature does not provide a completely adequate control for purposes of comparison, Griep, Barry and Hall⁷ have collected a group of 117 hypertensive patients who were first studied

at the University of Michigan Hospital ten or more years ago, and who were not treated with a splanchnicectomy. Six patients in this series had sustained a cerebral accident prior to the first examination. Of 4 women, 2 were still living ten and eleven years since the initial examination, the other two survived one year and eight years respectively. Both male patients were dead, having lived for seven and eight years respectively after their first examination. A cerebral accident was the cause of death in each case.

Brown⁸ has reported on 120 patients admitted to the Henry Ford Hospital, Detroit, between 1934 and 1939, each case clinically diagnosed as cerebral hemorrhage, an elevated blood pressure above 150 systolic and 100 diastolic was present in 90 per cent of the cases. He found that 65 per cent of patients recovered from their first cerebral accident, and 52 per cent from their second one. Only 10 per cent survived a third stroke, and the mortality was 100 per cent for a fourth stroke. The intervening time between strokes ranged from a week to eighteen years, and the average interval was two and a half years. This report is mentioned to point out that once a hypertensive cerebral accident occurs, recurrences are frequent and mortality increases with recurrence. Therapeutic effort to ward off recurrence of hypertensive apoplexy is thus warranted.

MATERIAL

During the ten years intervening between November, 1933, and November, 1943, more than 1000 hypertensive patients were treated by splanchnicectomy at the University Hospital, and 135 had previously sustained a definite cerebrovascular accident in which neurologic signs persisted for at least seventy-two hours. Cerebral incidents of shorter duration and episodes of hypertensive encephalopathy are not included. A duration of seventy-two hours is used to differentiate cerebrovascular accidents from cerebrovascular episodes.

*From the Department of Surgery, Section of Neurosurgery, University of Michigan Hospital and Medical School.

†This study was aided by grants from the United States Public Health Service and Mr. and Mrs. Albert Warner.

‡Professor of neurosurgery, University of Michigan Medical School.
§Research associate in hypertension, Section of Neurosurgery, University of Michigan Medical School; formerly instructor in internal medicine, University of Michigan Medical School.

Types of Cerebrovascular Accident

Sixty-six patients had sustained a hemiplegia, with coincident aphasia in 8. Hemiparesis had occurred in 50, a facial paralysis in 7, and aphasia alone in another 6 cases. There were 6 cases of spontaneous subarachnoid hemorrhage, the spinal-fluid findings in each confirming the diagnosis.

Age

The youngest patient was nineteen years, and the oldest was fifty-five years. Seventy-eight per cent

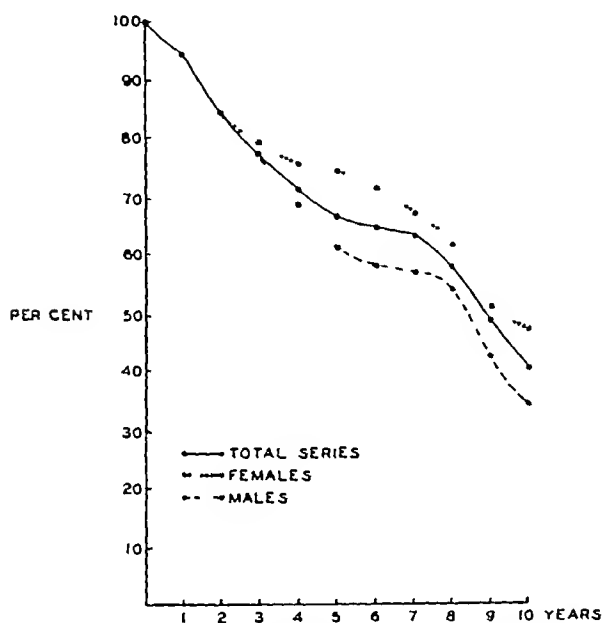

FIGURE 1. Curves of Yearly Survival Rates after Splanchnicectomy in 135 Cases of Hypertensive Cerebrovascular Disease

of this series were forty years and older at the time of the operation.

Sex

There were 73 male (54 per cent of the series) and 62 female patients.

Blood-Pressure Distribution

The average blood pressure ranged from 290 systolic, 178 diastolic, down to 170 systolic, 106 diastolic. Seventy-eight per cent had diastolic levels of 120 and higher.

Interval between Cerebrovascular Accident and Operation

Fifty-three per cent had a splanchnicectomy within six months of the cerebral accident, and 12.5 per cent were operated upon four to six weeks after the cerebral accident. The longest duration between apoplexy and operation was four years.

OPERATION AND OPERATIVE RISK

The operative procedure consists of bilateral resection of the greater, lesser and least splanchnic nerves, and excision of the lower thoracic sympathetic ganglions. During the first six years the operation was performed, only the lower thoracic dorsal ganglions were removed. Subsequently, ninth dorsal ganglions were also excised routinely. In recent years the operation has been extended to include a routine excision of the eighth dorsal ganglions. Higher ganglions, such as the seventh and fifth, are now frequently excised, depending on the technical facility in the individual case.

The anatomic dissection is carried out entirely above the diaphragm. This technic of splanchnic resection is performed bilaterally in one stage.

Three operative deaths occurred in this series of 135 hypertensive patients with cerebrovascular disease (operative mortality of 2.2 per cent). The patients were fifty-three, fifty-four and fifty-five years old, and in addition each had definite organic heart disease. The cause of death in each case was probably a cerebrovascular accident; autopsy, performed in 1 case, revealed thrombosis of the right middle cerebral artery and extensive recent infarction of the area supplied by the artery.

There were three additional postoperative cerebrovascular accidents, which the patients survived—cerebral thrombosis with left hemiparesis, a thrombosis of the anterior spinal artery and a left-facial muscle paralysis.

The operative mortality for hypertensive patients in general has been 1.6 per cent for those without papilledema, and 10 per cent for those with malignant hypertension.

SURVIVAL AFTER SPLANCHNICECTOMY

In this group of patients, each with a preoperative history of a definite cerebrovascular accident, the five-year survival rate for 62 female patients was 74.3 per cent, and the ten-year survival rate for 23 female patients was 48 per cent (Fig. 1). The five-year survival rate for 73 male patients was 61.8 per cent, and the ten-year survival rate for 23 male patients was 34.8 per cent.

For the entire series, the five-year survival rate was 67.3 per cent, the seven-year survival rate was 63.5 per cent, and the ten-year survival rate was 40.5 per cent. It should be noted that 16 cases with papilledema are included in this series.

Unfortunately the 6 cases of hypertensive cerebrovascular disease followed by Griep et al., in which operation was not performed constitute too small a group for purposes of comparison.

Forty-three patients, or approximately a third of the entire series, have suffered a recurrence of cerebrovascular accident during the long period subsequent to neurosurgical treatment, and 38 of these have died. Fifty per cent of the deaths in

series have been caused by recurrence of a cerebrovascular accident, 37 per cent of the deaths been due to congestive heart failure and primary thrombosis

FACTORS INFLUENCING SURVIVAL

It is well known that hypertensive disease is much more serious in men than in women. The women in this series also had a better survival rate than men (Fig 1). It is interesting to note that a recurrent cerebral accident was the cause of death in 70 per cent of the women who died. Yet only 10 per cent of the deaths among male patients were the result of another cerebrovascular accident, heart disease being the main cause of death.

Diastolic Blood Pressure

The mortality for the 135 patients with hypertensive cerebrovascular disease increased proportionately to the height of diastolic blood pressure at the time of operation. The five-year survival rate was 87.5 per cent for patients with diastolic levels below 120, 70.5 per cent for those with diastolic levels of 120 to 134, 66.5 per cent for those with diastolic levels of 135 to 149 and 46.5 per cent for the patients with diastolic levels of 150 and higher (Fig 2).

Retinal Hemorrhages

The presence of retinal hemorrhages at the time of splanchnicectomy adversely influenced the subsequent survival rate (Fig 3). The 64 patients with retinal hemorrhages had a five-year survival rate of 59.5 per cent, whereas the 71 patients without retinal hemorrhages had a five-year survival rate of 74.5 per cent. The ten-year survival rates were 29.3 per cent and 48 per cent, respectively. The preoperative fundoscopic examination through dilated pupils was performed in each case by staff members of the Department of Ophthalmology.

Heart Disease

Prolonged survival after a cerebral accident and subsequent sympathectomy is markedly dependent upon whether or not organic heart disease is coincidentally present (Fig 3). There were 107 cases in which definite heart disease existed at the time of the operation, this diagnosis in each was confirmed by an abnormal electrocardiogram or teleroentgenogram showing cardiac enlargement or both. The five-year survival rate for these persons was 58.8 per cent. On the other hand only 1 patient of the 28 with normal hearts died within five years of operation. The five-year survival rate for patients with previous cerebrovascular accidents but no coincident heart disease was 96.5 per cent.

Impaired Kidney Function

There were 51 patients with impaired kidney function, as evidenced both by an inability to concentrate urine to a maximum specific gravity of at least 1.020 on an eighteen-hour concentration test¹⁰ and by urea-clearance values of less than 60 per cent of average normal, these 51 persons had a five-year survival rate of 49.3 per cent. For 84 cases with normal kidney function, the five-year survival rate was 77.5 per cent. The 43 patients who had both heart disease and kidney disease coincident with the hypertensive cerebrovascular disease had a five-year survival rate of 41 per cent. There were 3 patients with azotemia at the time of the opera-

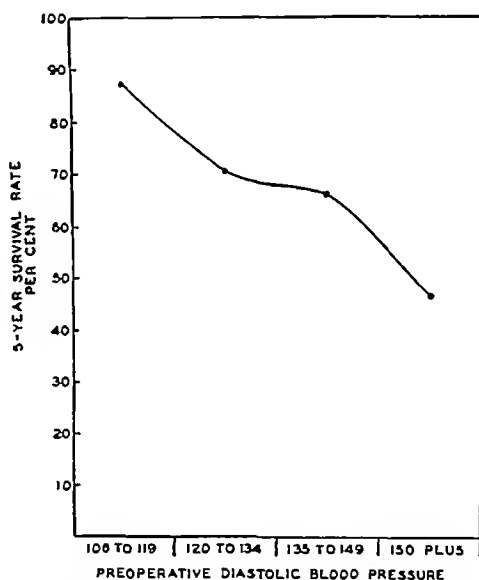

FIGURE 2 Influence of Preoperative Diastolic Blood Pressure on the Five-Year Survival Rate of 135 Patients with Hypertensive Cerebrovascular Disease

tion whose blood nonprotein nitrogen levels were above 40 mg per 100 cc, 1 case was an operative death, the second patient died within three months, and the third survived for three years.

Age

The mortality increased proportionally with the age at the time of splanchnicectomy (Fig 3). All 4 patients who were nineteen to twenty-nine years old survived for five years. The 25 who were in the fourth decade at the time of the operation had a five-year survival rate of 76 per cent, and those in the fifth decade a rate of 69 per cent. Fifty-four per cent of the 37 who were in their sixth decade survived for five years.

Interval Between Apoplexy and Splanchnicectomy

As long as the sympathectomy was performed within two years of the cerebral accident, post-operative survival was not appreciably influenced. But the 53 per cent five-year survival rate in the 30 cases in which two to four years elapsed between the stroke and the operation was definitely lower than that of the remainder of the series.

Factors of No Influence on Postoperative Survival

The presence of headaches, the occurrence of epistaxes, the neurologic findings subsequent to the

per cent, there has been no significant change from the preoperative diastolic-blood-pressure levels. Seventy patients, or the remaining 52 per cent of the series, are now dead, five to fourteen years after splanchnicectomy.

RATIONALE OF SPLANCHNICECTOMY

The influence of splanchnicectomy upon the cerebral circulation is an indirect one, for the operation does not denervate the cerebral arterial bed. Whatever benefit patients with hypertensive cerebrovascular disease may derive from a symp-

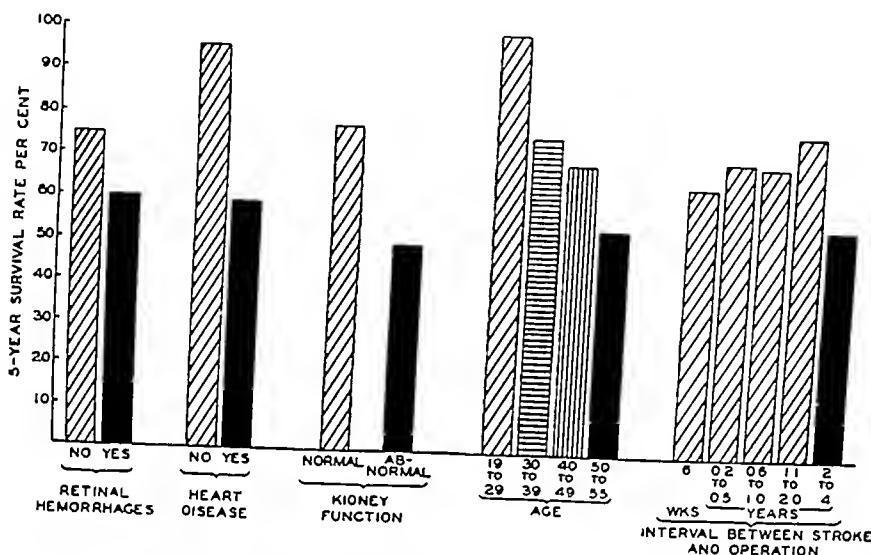

FIGURE 3 Factors Influencing Five-Year Survival Rate of 135 Patients with Hypertensive Cerebrovascular Disease Treated by Splanchnicectomy

cerebral accident, the complaint of vertigo and the known duration of elevated blood pressure prior to operation exerted no significant influence on the survival of the patients in this series.

BLOOD PRESSURE AFTER SPLANCHNICECTOMY

The 65 patients still living five to thirteen years after splanchnicectomy performed subsequent to a cerebral accident have recently been examined. Fourteen, or 10.4 per cent of the entire series, are maintaining normal blood-pressure levels of less than 150 systolic, 90 diastolic. Two of the patients maintaining normal blood-pressure levels were operated upon in 1937, each six months after a cerebrovascular accident, and the preoperative blood-pressure levels averaged 225 systolic, 148 diastolic, and 185 systolic, 120 diastolic, respectively.

In 41 cases, or 30.3 per cent of the entire series, significant reductions of 20 mm or more from the preoperative diastolic pressure have been maintained for five to thirteen years. In 10 cases, or 7.3

per cent, there has been no significant change from the preoperative diastolic-blood-pressure levels.

Seventy patients, or the remaining 52 per cent of the series, are now dead, five to fourteen years after splanchnicectomy.

thectomy must thus stem from an improvement in the general circulation following operation. It has been demonstrated in this series that the persons who continue to live a long time after splanchnicectomy without recurrence of cerebral accidents also continue to maintain significant reduction of their blood pressure, with only a few exceptions. In a previous study of cardiac aspects in cases of arterial hypertension treated by splanchnic resection,¹¹ it was found that there was significant improvement in electrocardiograms and decrease in heart size after operation.

In recent years it has been realized that certain dynamic, functional factors are involved in the production of brain-tissue damage from vascular causes. In addition to the occurrence of the histologic changes of hyalinization and thickening of cerebral blood vessels in hypertension, superimposed disturbances in the general circulation are responsible for the cerebrovascular accidents in this disease.

The reduction of blood pressure, the improvement of cardiac status and the decrease in pressor response to emotional and other stimuli after splanchnicectomy reflect the improvement in the general circulation that occurs in some cases. This approach to the cerebral circulation via the general circulation seems reasonable, until a more effective measure is available for long-range treatment of hypertensive cerebrovascular disease.

DISCUSSION

As yet no definite statement can be made whether the surgical procedure of splanchnicectomy has beneficially altered the course and prolonged the lives of patients with hypertensive cerebrovascular disease. The literature does not contain a sizable series of hypertensive patients followed after surviving a cerebral accident. No control group is available for a proper comparison.

That some patients with hypertensive cerebrovascular disease pursue a rather rapid downhill course with a short duration of life is pointed out by Taylor and Page¹². They studied 40 patients who died of hypertensive disease (19 of cerebral hemorrhage) to uncover facts that might aid in predicting whether a patient with essential hypertension is likely to have a stroke. Five findings were especially common among those who died of cerebral hemorrhage: severe headache, vertigo or syncope, motor or sensory neurologic disturbance, epistaxis and retinal hemorrhages. Those who died of cerebral hemorrhage lived an average of two years and one month after the first symptom of the ultimate cause of death, the duration of life from the appearance of the first neurologic sign averaged only a year and a half.

Newbill¹³ determined the duration of life after cerebrovascular accidents in 296 cases found in the 10,903 consecutive autopsies performed at Charity Hospital, New Orleans, between 1929 and 1938. Only 16.9 per cent of patients lived one month or longer after apoplexy, and only 1 survived longer than a year. Naturally, studies based on autopsy reports can only present the most unpleasant view of a clinical picture.

The survival statistics of our series of hypertensive patients with cerebrovascular disease treated by splanchnicectomy appear good, but decision whether the operation has beneficially modified the course of this aspect of hypertensive disease must await valid comparison with an appropriate control. The ultimate worth of the neurosurgical treatment of arterial hypertension can best be evaluated by determination of its influence on the natural life history of this disease.

SUMMARY

The surgical procedure of bilateral supradia-phragmatic splanchnicectomy has been utilized in the treatment of 135 hypertensive patients who had already sustained a definite cerebrovascular accident, in the attempt to alter beneficially the course of their disease.

These patients have now been followed for a long time, and it has been found that the five-year survival rate for the entire series (in which male patients predominate) was 67.3 per cent, and that the ten-year survival rate was 40.5 per cent. The female patients had better survival rates than the males.

Survival in hypertensive cerebrovascular disease is adversely influenced by the presence of retinal hemorrhages, high diastolic blood pressure and heart disease, the coincidence of impaired kidney function, the advancing age of the patient and an interval of longer than two years between the stroke and the splanchnicectomy.

Fourteen patients who had previous hypertensive cerebral accidents were maintaining normal blood-pressure levels five to eleven years after operation.

Approximately a third of the entire series suffered a recurrence of cerebrovascular accident during the long period subsequent to neurosurgical treatment, and 50 per cent of the deaths were caused by such recurrences.
